It is often very desirable to throw the centre of the mirror a good deal to one side of the axis of the body of the microscope, so that the reflected rays may fall very obliquely upon the object, and cause its prominences and depressions to exhibit shadows of much greater depth than can ever be seen with more direct light. No microscope, in which there is not a provision for this movement, can be regarded as having its resources properly developed; and we have seldom seen one which comes up to our ideas of the degree in which it should be permitted. In general, the mirror-frame is immediately fixed to the sprung tube which carries it; and thus it can only be turned out of the axis at an angle which will evidently interfere with its use. In our own microscope, the mirror-frame is connected with the tube by a stalk of an inch in length, so that the centre of the mirror is three inches from the stem. This, of course, involves a lengthening of the stage, and of the arm which carries the body, in order that the centre of the apertures of all three may be in the same line; but the disadvantage hence resulting is easily avoided by increasing the strength of these parts. The variety of illumination which may be given by a mirror fitted in the manner we have described, is very great; and some very curious and unexpected phenomena are not unfrequently disclosed by means of it. For example, the field may be rendered almost dark, by turning the centre of the mirror considerably out of the axis, so that none of the rays reflected by it pass up the body of the microscope; whilst objects of great delicacy will frequently appear brilliantly illuminated, on account of their retention of a part of the light which is passing obliquely through them. In this manner we have often been enabled to see an immense number of the minutest animalcules (monads) rapidly moving through water, in which, with direct light, none but the larger ones could be distinguished; and the interest of the spectacle is heightened by the phosphorescent glow which the animalcules appear to have when thus illuminated.* A similar effect may be produced without the use of the concave mirror, by causing a direct pencil of rays from a lamp or candle to be thrown very obliquely upon the object by means of a condensing lens.

In the examination of many delicate objects with high powers, direct light will often be found more advantageous than reflected. This may be obtained with facility, by placing a lamp or wax-candle behind the stage, the mirror being turned out of the way. In the day-time the direct light of a bright cloud will often be found to produce an extremely beautiful effect; but in order to attain this without an inconvenient position of the head, the microscope stand must be elevated to such a height, that, when the stem is horizontal, or even inclined in a position contrary to the usual one, the eye-piece may be at a convenient height for the eye. The different modes of illumination best suited to different objects can only be found out by experience, since achromatic objectives vary in their relative effects with each.

* This method of viewing objects was publicly noticed, a few years since, as a new discovery; it had long, however, been familiar to ourselves, and, we believe, to most other scientific observers.

When condensed light is employed with deep powers, great care is necessary in order to bring out the best effects of a microscope, with difficult objects. These remarks apply to the simple as to the compound forms of the instrument. We do not ourselves consider the *ordinary* condenser as of much more value for the higher than for the lower class of transparent objects; and we think that it may be discarded from the instrument without disadvantage. Great assistance may be obtained, however, from a well-constructed condenser, in the resolution of the more difficult class of microscopic objects. That which was proposed by Dr. Wollaston for use with his doublet consists of a tube about six inches long, having at the lower end a diaphragm with a circular perforation about three-tenths of an inch in diameter, through which light, proceeding from a radial point or surface, is reflected by a mirror below it. At the upper end of the tube is a plano-convex lens, about three-fourths of an inch focus, with its plane side next the observer; the object of which is to form a distinct image of the circular perforation in the plane of the object, which should be at about eight-tenths of an inch from the lens. We consider this instrument to be theoretically faulty; inasmuch as the point from which the illuminating rays diverge, and the limiting aperture are not coincident, so that pencils brought to a focus for the former are not for the latter. The length of the tube, again, is an inconvenience, especially in the case of small microscopes. Nevertheless, it is much superior to the ordinary form of condenser. An improvement was suggested by Dr. Goring, which consisted in shortening the tube below the lens, and removing the stop from that end of it to the other, so that it should be just beneath the object; in this manner the illuminating rays may be brought to a focus on the object, the superfluous ones being cut off by the stop. We have derived much advantage from the use of this condenser in the small doublet microscope already noticed, and by a slight modification of it we can obtain a variety of illumination, which is often very useful. Our condenser consists of three tubes, one sliding within the other; the outer one is fixed to the under side of the stage; the second carries at its upper end the stop, the distance of which from the object may thus be changed, and the inner one carries the condensing lens. A stop may be screwed into the bottom of the latter, if it is desired to adopt Dr. Wollaston's plan. We have derived the greatest advantage from the use of this condenser, however, by using it with direct light from a radiant point at some distance,—a bright cloud, for instance, in the day-time,—and a lamp or candle on the opposite end of the table at night. In either of these cases, the focus of the illuminating rays may be made coincident with the plane of the object, without that glare which will almost certainly be produced if the source of light is nearer and more intense. When thus used, Dr. Goring's condenser approaches in its character to that of Sir D. Brewster,* which we shall now describe, adding some ideas of our own in reference to its construction.

The principle of illumination on which Sir D. Brewster lays great, and we think fully-deserved stress, is, that the focus of the illuminating rays shall be coincident with the object, so that there shall not be two sets of rays at different angles, one proceeding from the luminous object and the other from the object to be magnified. This can only be attained in any degree by making the image of the illuminating body coincident with the object; and it will be perfectly accomplished, in proportion as the rays forming that image are themselves free from aberration. If, for example, the white rays have been separated into their component colours by the condenser, these colours will be imparted to the object, the appearance of which will also be rendered less distinct by the spherical aberration of the condensing lens. Hence *an achromatic lens*, or, if this be objected to on account of its expense, a Herschel's aplanatic doublet, should be used as the condenser; the latter we have found to answer very well, as the centre of the circle illuminated by it is very nearly free from false colour. Further, if a mirror be employed to change the course of the rays, it should be of metal, in order to avoid the false rays reflected from the first surface of the glass. If day-light be employed, no other precaution is necessary; but if the illumination be obtained from a lamp or candle, it will be necessary to limit the amount of light admitted. This must not be by a stop placed beneath the lens, for the reason already specified; but it should be accomplished by a stop or shade placed as *near as possible to the flame*, so that the image of that and of the flame may be brought—virtually if not exactly—to the same focus. We have found that the same end may be attained by removing the lamp or candle to a greater distance, so as to diminish the intensity of the light to the required amount, and only a very low flame will then be required, as the condensation of the rays is much more perfect than with the ordinary lens. The achromatic condenser is strongly recommended also by M. Dujardin, an eminent microscopist of France; and we know that it is now considered an indispensable addition to microscropes of the highest class, affording, as it does, the means of resolving objects, previously considered too difficult to admit of a clear view of their nature. We are disposed to think, however, that some improvement is necessary in order to develope the *highest* powers of this instrument. The rays of light proceeding from the radiant point or object, being brought to a focus by the condenser on its surface, cross each other there, and should proceed to the object-glass of the microscope, as if they came from the object itself. Now, unless they are made to converge upon the object at the same angle at which they diverge

* Treatise on the Microscope, from the Encyclopædia Britannica.

to enter the objective, we cannot but think that a source of error still remains, and that the most perfect image possible, formed by an achromatic object-glass, of an object which is artificially illuminated, can only be produced when the rays from the source of light take exactly the same course as if they proceeded from the object itself. That they may have this course, they must be made to converge upon the object by a condensing lens, whose focus for parallel rays (if the illuminating point be very distant) shall be the same as the acting focus of the objective. A different condenser would thus be required for every objective; but the expense of these would be sufficient to preclude their general employment. The same condenser might be employed, however, for several low powers; the highest having their own expressly adapted to them. We may mention it as a fact for which we cannot very well account, that we have been able to obtain a very beautiful and distinct illumination by the use of an aplanatic-doublet condenser, receiving its rays from the ground glass globe of the common table-lamp, which would not seem to furnish any of the conditions that we have dwelt on as of theoretical importance.

Opaque objects may be illuminated in two principal ways, either by a light cast obliquely upon them by a condensing lens, or by rays thrown upon them perpendicularly by a silver speculum fixed to the object-end of the body, which receives them from the mirror below. Both these modes have their peculiar advantages, and will be found by experience to be applicable with advantage to different classes of objects. No general directions on the subject can, however, be given. The condenser to be used by lamp-light for large opaque objects should be a bull's-eye or hemispherical lens of four inches in diameter; by this, even from a common candle or flat-wicked lamp, a sufficient light may be attained for almost any purpose, and with an Argand lamp a very powerful illumination is obtained. For the parallel rays of day-light, however, an ordinary double-convex lens of the focus of two inches or more may be employed; this may be mounted upon a separate stem and foot, as the bull's-eye should always be, or it may be attached to some part of the microscope itself. We have seen foreign instruments in which it was fixed to the object-end or nose of the body; a construction which we deem essentially bad, inasmuch as it then requires to be readjusted every time that the focal distance is changed by the substitution of one objective for another. A better mode in our opinion is to attach it to the side of the stage by a jointed arm possessing a pin which may be fitted into one of three or more holes drilled in the *side* of the stage with sufficient tightness to remain in any position. If the wire to which the lens-frame is attached be made to pass through a sprung socket connected by a ball-and-socket-joint with the jointed arm, an immense variety in position may be readily given to the condensing lens, which will render a separate mounting for it unnecessary.

The metallic speculum, or Lieberkuhn, for throwing down rays directly upon the object, is sometimes attached to the objective itself, sometimes to a tube which may be drawn down over it to the required amount. The former construction is the most perfect, each magnifier having its own speculum; but the latter is most economical, as one speculum serves for many objectives. When the latter construction is employed, the tube should be marked with the numbers of the magnifiers at the points at which it may be best adjusted for each, so that, when the object is in the focus of the objective, it may be in full receipt of the rays reflected from the speculum. In this mode of illumination the size of the concave mirror will be found to have a considerable influence; and the capability of adjusting also its distance from the speculum gives a useful variety to the mode of illumination. It can never be too fully kept in mind, that, in the examination of doubtful objects, no really satisfactory result can be attained, until they have been viewed in every possible way. When the object is not perfectly opaque, or does not fill up the whole of the field of view, it should always be placed on an opaque disc, which should be large enough to interrupt all the rays passing directly upwards from the mirror to the eye. The colour of this disc may be advantageously varied for certain objects, but in general we consider a dead black the best for giving them effect. As a general rule it may be remarked, that the fewer the rays entering the eye *except* through the object, the more perfect will be the view of it; and if there be anything approaching to a glare around an opaque object, whether the light proceed directly from the mirror, or be reflected back from the too-bright surface of the disc, it is equally injurious, and will occasion a mistiness over the object itself. It is evident, however, that the size of the disc must be governed by that of the field of the objective employed; for, if too large, it will interrupt too much of the light impinging on the speculum. A piece of black glass, mounted upon a long strip of common window-glass, will be found very useful where the object is such that it can be laid upon it when the microscope is inclined. When the object requires to be held in the stage-forceps, however, a disc of black card may be placed behind it, so as to afford it a back-ground. And for some delicate opaque objects, it is most advantageous to employ little concave discs or cups, with their interior blackened, in front of which the objects are to be placed. Similar dark backgrounds are useful when oblique light is employed.

III. Magnifying power of microscopes.

The next point to which we shall advert is the mode of estimating the magnifying power of microscopes, and of measuring the real size of objects under examination. Our estimate of the magnifying power of a microscope must depend upon the standard which we assume as the ordinary distance at which the object is seen with the naked eye; since, if brought within five inches, it is seen under double the angle, and therefore of double the size which it appears to possess at ten inches. If, therefore, the former distance were taken as a standard, the magnifying power of a lens or microscope will only be half that at which it would be estimated with reference to the other. Nearly all opticians, however, have agreed in considering ten inches as the standard of comparison; and when, therefore, an object is figured as magnified 100 diameters, it is meant that this figure placed at ten inches distance from the eye is 100 times the dimension, each way, of the real object seen with the eye alone at a similar distance. The measurement of the magnifying power of simple or compound microscopes by this standard is attended with no difficulty. All that is requisite is to have a glass or thin slip of ivory accurately divided to a small fraction of an inch ($\frac{1}{100}$th will usually answer very well), and a common foot-rule, divided to tenths of an inch. The glass or ivory micrometer being adjusted to the focus of the magnifier, the rule is held parallel with it, at the distance of ten inches from the eye. If the second eye be then opened, whilst the other is looking at the object, the circle of light included within the field of view, and the object itself will be seen faintly projected upon the rule; and it will be very easy to mark upon the latter the apparent distances of the divisions on the micrometer, and thence to ascertain the magnifying power. Thus, supposing that each of the divisions of $\frac{1}{100}$th of an inch corresponded with $1\frac{1}{2}$ inch upon the rule, the linear magnifying power is 150 diameters; if it corresponded with half an inch, the magnifying power would be 50 diameters. The superficial magnifying power is of course estimated by squaring the linear; but this is a mode of statement never adopted by scientific observers, although often employed to excite popular admiration or to attract customers by those whose interest is concerned in doing so.

When the magnifying powers of the several objectives of a microscope are known, it is easy to make a fair approximation to the real size of an object under examination, by projecting its image, as before, upon a foot-scale held at ten inches distance; and the apparent dimensions it there exhibits, divided by the magnifying power employed, will of course be its real size. More accurate measurements are generally required, however, although the foregoing may serve as a sufficiently near approximation for ordinary purposes. Various methods of obtaining these have been devised. The most perfect measurements are obtained by a fine micrometer-screw, by turning which either the object or the body will be made to execute a transverse movement; just as, in the fine adjustment of the focus, the body is made to approach or recede from the stage. This apparatus may be attached to the stage, if it be thought preferable to move the object, or to the arm if the body be made to traverse. In proportion to the fineness of the screw, and to the size of the milled-head, will measurements be obtained of minute accuracy. In the focus of the eye-piece a very fine thread is placed; and one edge of the image being brought against it, the position of the micrometer is noticed; and the other edge being then brought to the same line, the number of divisions of the micrometer-screw, which have passed over the index, will indicate its size. The expensiveness of this micrometer, when made with sufficient accuracy and minuteness, is the only bar to its general employment. Other means have been devised, however, which are scarcely inferior; and the simplest of these requires only the use of an eye-piece of a construction different from the ordinary, with coarsely divided glasses. The micrometer eye-piece is made upon the principle of Ramsden's. The optical part of it differs from that in common use, in having the plane side of the field-glass turned towards the object; and in the adjustment of the foci of its lenses in such a manner that the image to be viewed by it must be beneath the field-glass instead of being between it and the eye-glass. In its focus there is placed a plane glass with divisions on it; these may be from $\frac{1}{20}$th to $\frac{1}{100}$th of an inch apart; the latter will enable very minute measurements to be taken. By this arrangement, when the object is brought into focus, it appears as if it were traversed by cross lines; since its image is coincident with the divided glass, and is, like it, viewed by the eye-piece as by a simple microscope. The *value* of these divisions will, of course, depend upon the degree in which the object is magnified in the image; and they must be ascertained for every objective, by the divided glass or ivory micrometer. This being brought into focus, and so placed that the direction of its two sets of lines shall correspond with those of the divided glass in the eye-piece, the number of divisions in the latter, corresponding to each division of the former, must be observed, and their value will be thus ascertained. Thus, if one division on the $\frac{1}{100}$th inch micrometer be found to coincide with eight on the eye-piece, these eight will together indicate a dimension of $\frac{1}{100}$th of an inch upon the object; and each division of the eye-piece will of course be equivalent to the $\frac{1}{800}$th of an inch. If there is not an exact correspondence, or if it be desired to obtain a power which can be expressed in round numbers, a little alteration in the length of the body, made by drawing out his eye-piece, will enable the microscopist to effect this; but the eye-piece should be marked, so as to be adjustible to the same point again, when the same magnifying power is employed. When the value of the divisions on the glass in the eye-piece is ascertained for every magnifier, the object-glass micrometer may be put aside altogether; since by the use of the eye-piece alone, a series of lines, the real distance corresponding to which is known, is projected upon the object; and, with a little practice, a very close estimate may be formed of the proportional size of the object, when it only extends over a part of a single division. This, for ordinary purposes, is by far the most convenient mode of measurement.

The camera lucida, however, which has been adapted to the microscope for the purpose of delineating representations of microscopic objects, may be most advantageously applied also to micrometry. By this instrument (of the construction of which we shall presently speak) a highly magnified picture is projected upon a surface on which its outlines may be easily marked, and on which their size may, therefore, be determined with the greatest nicety. Here, as in former cases, the micrometer object-glass must first be employed, in order to fix the standard. If one of these be placed in the focus of the microscope, and the camera lucida be so adjusted, that an image of its lines be thrown upon a piece of paper at a fixed distance from it, the distance of these may be marked with precision; and subdivision on the paper may be carried to any required extent, so as to afford the means of at once ascertaining the size of an object placed in the field. Thus, if the magnifying power and the distance of the paper be so adjusted, that the lines which are really $\frac{1}{100}$th of an inch apart are projected upon it at five inches distance from each other, every inch on the paper will of course be equivalent to $\frac{1}{500}$th of an inch on the object. Lines of $\frac{1}{20}$th of an inch apart may easily be drawn on the paper; and the distance between each of these will represent $\frac{1}{10000}$th of an inch on the object. In this manner the size of an object may be known with great nicety, and with less liability to error than in the use of the screw micrometer. It is easy to increase the apparent size of the image thrown by the camera lucida to almost any required extent; so that even greater minuteness may be attained. The distance between the eye-piece and the paper may be increased,—either vertically by placing the latter upon a chair or even on the floor,—or horizontally, by turning the prism or mirror a quarter round, and projecting the image in the direction of the side of the room, so that the range of distance is much increased. Such a plan is, of course, of no use in delineation; but in micrometry it may be had recourse to with advantage, especially when comparing the relative sizes of similar objects, such as the blood-discs. For every magnifying power, whether gained by changing the objective or by increasing the distance of the screen, a determinate value must of course be ascertained for the divisions of the latter.

The camera lucida of Dr. Wollaston is sometimes applied to the eye-piece of the microscope for the purpose of delineation and micrometry; but it is much inferior for these purposes to other plans which have been devised. Probably the best of these consists of a mirror composed of a thin piece of rather dark-coloured glass cemented on a piece of plate-glass, inclined at an angle of 45° in front of the eye-glass. Of the light which passes out from the latter, a sufficient quantity is reflected by the mirror to give a distinct image; and yet the paper and pencil can be distinctly seen through the glass, though rather darkened by the coloured glass, which thus serves to render the image more brilliant. A lens is placed below the reflector, which causes the rays from the paper and pencil to diverge at the same angle with those received from the eye-glass; so that both the object and the pencil are seen with equal distinctness. The use of a small highly-polished steel mirror, fixed in the focus of the eye-piece, and inclined upwards towards the eye at an angle of 45°, is by some preferred to this. The mirror being smaller than the pupil allows the rays from the paper to pass up into the eye around it; and thus the image is seen as upon the screw. In the use of either of these instruments, the chief difficulty (as in the use of the common camera lucida) is for the delineator to see both the image and pencil with sufficient distinctness to enable him to make an accurate tracing of the former. Much will depend upon the advantageous adjustment of the amount of light upon the object and the paper respectively. In drawing or measuring by lamp-light, we have found it useful to place a small taper near the screen, so that its direct rays may fall upon it, whilst the lamp is used for illuminating the object; and when the screen is illuminated by daylight it is preferable still to use the lamp for the other purpose. The point of the pencil should be blackened. The micrometer eye-piece also may be employed for drawing; its squares being represented by squares on the paper; and the portion of the object between each being delineated, in the manner commonly practised by artists. No assistance of this kind, however, can supply that skill to the microscopic draughtsman which is required for making finished delineations of any object. Accuracy of outline is all that they can ensure.

Under this head it seems not inappropriate to introduce a few remarks on the degree of minuteness in the structure of objects, which the magnifying power of the microscope enables us to detect.

Much speculation has taken place amongst philosophers at different times, relative to the possibility of detecting the *ultimate atoms* of material, especially organic, substances; and microscopists have occasionally hazarded statements in regard to their size, which an increased knowledge has shown to be invalid. It was a favourite theory about fifteen years since, that all organized bodies are made up of globules, which cannot be resolved into any other kind of structure, the diameter of which was stated at about $\frac{1}{8000}$th of an inch. The great improvements which have been recently made, however, in the microscope, and the general advance of knowledge on the subject of the ultimate constitution of organized structures, have shown the erroneous nature of this view, by proving that there is no body, however minute, which is not capable of being resolved into smaller particles, as far as our means of observation can carry us; and the absurdity of the particular dimensions assumed is further shown by the fact, now well known, that there are very numerous species, and countless individuals, among the Polygastric animalcules, whose whole bulk is much less than that of one of the so-called ultimate particles, and which contain within this a considerable number of different organs. The following statements made some years since by Ehrenberg will give a very good idea of the mode in which the size of such organs and of their component parts may be approximately known, when they are themselves too minute for measurement.

"I could plainly distinguish with a microscope magnifying nearly 800 diameters, Monads, which were filled with colouring nutritive substances, and which possessed voluntary motions, but the entire and greatest diameter of whose body only amounted to the $\frac{1}{1500}$th or $\frac{1}{2000}$th of a Parisian line. I could perceive in the largest individuals of this form as many as six, and in the smallest as many as four, internal sacs coloured blue by indigo, which at times did not occupy half the internal dimension of the animal. Such a sac, therefore, of an animalcule measuring $\frac{1}{1500}$th of a line, and if we suppose only four sacs occupying the half of it, (therefore not one of the smallest,) is $\frac{1}{12000}$th of a line in size. Further, if we suppose the single colouring particles, with which the stomachs are filled, not to be numerous, it would be against all probability not to think that they were filled by several particles. Let us, however, only suppose each sac to be filled with three colouring atoms,—which, from the roundness made perceptible by the motion communicated to them when diffused through the water, we may well admit,—this alone affords a proof of the existence of material colouring particles of red and dark blue moving freely in water, which measure $\frac{1}{36000}$th of a line, or $\frac{1}{432000}$th part of an inch in diameter; and calculating these objects from the smallest of the animalcules, which by actual observation were found to be $\frac{1}{2000}$th of a line in size, and which sometimes contained four coloured points in the hinder part of the body, these particles, which cannot be distinguished individually by the eye with a magnifying power of 800, but which are yet to be recognized as corporeal, would amount to $\frac{1}{48000}$th of a line, or $\frac{1}{576000}$th of an inch. Further, the smaller monad-stomachs are seen isolated in the body, and with sharp outlines. In larger Infusoria, which are $\frac{1}{48}$th of a line, or more, in diameter, these internal receptacles are recognized as evident membranaceous sacs, which often make their appearance isolated, when the animalcule is pressed, or when it divides itself, and which have been supposed to be separate infusoria, internal monads. It can be distinctly seen that, when two such digestive sacs touch one another, the thickness of the partition between them is, in comparison with the diameter of the stomach, extremely small, so that the former is scarcely perceptible; it may be reckoned as at the most $\frac{1}{20}$th of the latter. Granting, however, the thickness of the partition to be as much as $\frac{1}{10}$th the diameter of the sac, this would amount to $\frac{1}{160000}$th of a line, or $\frac{1}{1920000}$th of an inch, in monads $\frac{1}{2000}$th of a line in size, in which the stomachs measure but one-eighth of the whole length of the body, and are therefore $\frac{1}{16000}$th of a line in diameter." When similar views are extended to the young of the species on which this calculation is founded, or to smaller species in the existence of which there is good reason to believe, the minuteness of structure thus disclosed becomes still more wonderful. "Let not these calculations," it is justly remarked by Ehrenberg, "be regarded as playful; they are so far in earnest, that they are founded on the contemplation of nature, and are not to be considered as a groundless speculation. They plainly demonstrate an unfathomableness of organic life in the direction of the smallest conceivable space; and if the word infinity be too much for what we know at present, let the word unfathomableness, which I have purposely employed, avert from me the reproach of exaggeration, and establish the direction which the physical, chemical, and physiological enquiries of our days, should they be rendered fruitful by new powers, have to take, and what deviations they have to avoid."

To these enquiries Ehrenberg has subjoined an attempt to calculate the power of vision for the human eye, and the ultimate power of the microscope. From his experiments on the smallest square magnitudes which are ordinarily visible at any distance by the human eye, he finds that they vary in different cases from $\frac{1}{36}$th to $\frac{1}{108}$th of a line; but when strongly illuminated, much smaller bodies can be seen, metallic particles of $\frac{1}{100}$th of an inch being visible in common daylight; and non-transparent threads of $\frac{1}{400}$th of a line in thickness being distinguished, when held between the eye and the light. Hence the size of the minutest objects visible with a given magnifying power of the microscope might be determined by dividing their apparent dimensions, as just stated, by the magnifying power; thus no square corpuscles of less dimension than $\frac{1}{3600}$th or $\frac{1}{4800}$th of a line could be seen with a magnifying power of 100 diameters. In practice, however, owing to the degree of imperfection which must necessarily attend the best-constructed instruments, the minuteness of the smallest visible objects cannot be judged of entirely by this rule; since, in order that it should be correct, it is necessary that the object of $\frac{1}{4800}$th or $\frac{1}{3600}$th of a line in diameter, should be represented to the eye as clearly by a microscope magnifying 100 diameters, as a real object of $\frac{1}{48}$th or $\frac{1}{36}$th of a line would be; this is very far from being the case, owing to the loss of light by reflection in passing through the lenses, as well as to the errors of the lenses themselves, which can never be perfectly corrected. With a magnifying power of 1000, which is perhaps the highest that has yet been employed to real advantage, the minutest particle which could possibly be distinguished would be $\frac{1}{36000}$th or $\frac{1}{18000}$th of a line square, and thus they would be much larger than those of whose existence a very simple process of reasoning is sufficient to convince us.

MILK.—(Γαλα, Gr.; *lac,* Lat.; *le lait,* Fr.; *die Milch,* Germ.; *latte,* Ital.) The secretion of the mammary gland. In treating of the milk it will perhaps be best, previous to entering upon its description as produced by the human subject, to give a general account of the secretion as obtained from the cow, such being the most familiar example afforded to us. Milk may be regarded as a serous fluid, holding in suspension minute white globules composed of casein and fatty matter. These globules have been microscopically examined by Raspail, who states them to have a diameter of .00039 inch, and to disappear on the addition of a solution of potassa. The most recent microscopic observations on the milk are those of Professor Nasse, of Marburg,* who gives the following as the constituents of the normal secretion of the mammary gland:—1st, smooth, homogeneous, transparent oil globules and large oil globules, also the common milk globules; 2d, cream globules, distinguishable by their facette-like appearance; 3d, granulated yellow corpuscles; 4th, the lamellæ of epithelium; 5th, the more or less turbid medium in which the four preceding kinds of corpuscles are suspended.

The *common milk globules* are composed of fatty matter, which dissolves rapidly in ether. No membrane can be seen investing them. The first nine days after delivery the largest globules measure $\frac{1}{200}$th of a line in diameter, but subsequently become as large as $\frac{1}{100}$th, but they vary in size throughout lactation. The *cream globules* are considered by Professor Nasse to be formed after the milk has been drawn or exposed to the air, for in fresh woman's milk no globules but the common milk globules above described are discernible: the cream globules occur as large as $\frac{1}{50}$th of a line in diameter. The *yellow granulated corpuscles* are peculiar to the colostrum; their diameter is from $\frac{1}{100}$th to $\frac{1}{200}$th of a line; some are found measuring $\frac{1}{30}$th of a line in length and $\frac{1}{73}$th in breadth. They are composed of fatty matter. The author considers them analogous to the mucus cells cast off from mucous membranes, and thinks that perhaps they come from the gland ducts. From my own observations I am inclined to think that the cream globule of Nasse exists even in fresh milk, and may easily be seen in specimens containing but little fatty matter. I lately saw them in the milk of a woman who had suckled for seven months. I have not been able to rid the milk of globules by ether or liq. potassæ. If milk be agitated with ether, then allowed to stand, and the lower stratum of fluid examined, we can detect distinct globules in it—globules of all sizes, and having the appearance described by Nasse as belonging to the cream globule. From the variety in size which I have so constantly observed, I cannot understand how any author can have made up his mind to give an admeasurement to the globule of milk; for my own part, after much careful observation, I feel convinced that the milk contains nothing which deserves the name of a true organic globule. That globules exist I do not deny, and these I believe to be what have been described by Nasse as cream globules, appearing when milk has creamed, because the adhering fatty matter is separated; but, notwithstanding, being very obvious before creaming occurs, in specimens of fresh milk containing a small proportion of fatty matter. The serum in which these particles float is composed of water, holding in solution an alkaline lactate and chloride with traces of sulphate and phosphate, lactates of lime and magnesia, sugar of milk, and animal extractive. Oxide of iron and an earthy phosphate are to be detected in the ashes of milk, but these, in all probability, are derived from the casein of the secretion. When milk is allowed to remain at rest for some hours, a pellicle forms on its surface, varying with the nature of the milk: this is what is called the cream, and consists of the fatty or butyraceous matter of the milk in combination with a varying proportion of casein. It is from this cream that butter is obtained by churning, by which operation the butyraceous particles unite into a mass to the exclusion of the casein, which remains suspended in the serum, and thus forms a mixture known by the name of butter-milk or lait de beurre of the French. The whole of the casein, however, cannot be removed from the butter by churning, its minute particles being entangled by the cohering fatty globules, and it is in a great measure owing to its presence that butter is more or less prone to become rancid and decomposed. Milk from which the cream has been removed still retains the greater part of the casein, and when this is precipitated from it by the action of rennet, we obtain a curd, which, being pressed and dried, constitutes cheese. The clear liquor separated from this curd contains the more soluble matters of milk, viz. the alkaline salts with the sugar of milk, and in Switzerland a considerable quantity of this sugar is manufactured from whey and used for household purposes. I have thought it best to notice the various operations in domestic economy to which the milk is subjected, not only because by them several of its proximate elements are eliminated, but likewise that the reader may have some familiar object with which to connect the following account of the

* Müller's Archiv, 1840, Heft iii. p. 258.

chemical properties of the constituents of the fluid.

The fatty matter of milk obtained by churning cream, and which is known by the name of butter, differs from the other forms of animal fat in several particulars. It yields about 88.5 per cent. of fixed acids on being saponified, for which purpose it requires no more than four-tenths of its weight of caustic potassa; it therefore unites with alkali very easily. Of these acids the margaric and oleic are in large proportion, the stearic existing as a mere trace. Glycerine, as is the case with other fats, is a constant product of the saponification of butter. The great distinguishing peculiarity of this form of fatty matter consists in the production of three volatile acids as results of saponification; these have been carefully examined and distinguished by Chevreul in his admirable work, "Sur les Corps gras." He has named them the butyric, caproic, and capric acids. The production of these acids by the action of alkali has been traced by Chevreul to the existence of a new form of fat which he detected in butter mixed with the stearine and elain, and to which he gave the name of butyrine: thus butter may be regarded as composed of three different kinds of fatty matter—stearine, elain, and butyrine—the two former yielding by saponification the margaric, oleic, and stearic acids, and the latter the three volatile acids above mentioned. The proportions of the three kinds of fat vary considerably in different specimens of butter. The solubility of butter in alcohol is stated by Chevreul to be 3.46 parts in 100 at a boiling temperature, the specific gravity of the menstruum being 0.822. The stearine obtained from the alcohol by cooling is more crystalline and of a more brilliant white than that obtained from common fat, and 1.45 parts require 100 parts of alcohol of specific gravity 0.822 for its solution. The elain obtained from butter possesses no peculiar characteristics. The butyrine when separated from it, which is only to be accomplished with difficulty, possesses the following qualities:—it is an oil generally of a yellow colour, but some specimens of butter yield it perfectly white; it concretes at 32° Fahrenheit, and possesses the smell and taste of butter; it mixes with boiling alcohol in all proportions; it is soluble in anhydrous alcohol. Potassa and the other alkalies are not the only substances capable of producing the volatile acids by acting on butyrine. Alcohol if long digested produces a similar effect, as does strong sulphuric acid, and if butyrine be allowed to putrify these acids are developed.

The casein or cheesy matter of milk which is obtained with some slight admixture of the fatty matter in the production of cheese from the skimmed milk has the following chemical properties. It is soluble in water after long digestion; but this is most likely owing to some decomposition which occurs in it, and it is certain that casein in its pure, undecomposed, and dry state is quite insoluble in water. Casein, as it exists dissolved in skim milk, is precipitable by the mineral acids and also by the acetic acid. The process which Berzelius recommends in order to obtain this substance is as follows:—Skim milk is to be mixed with a small proportion of dilute sulphuric acid, which unites with the casein and precipitates it in the form of a white clot. This is to be well washed with distilled water on a filter in order to separate the whey which it contains. After this carbonate of baryta and water are to be mixed up with the mass, by which means the acid is separated and the casein remains dissolved in the water, and may be separated from the carbonate and sulphate of baryta by filtration. Casein obtained by this process is more or less soluble in water, and is precipitated from its aqueous solution by the acids. It rapidly undergoes the putrefactive fermentation. It is soluble in the alkalies and in alcohol both boiling and cold, but far more so in the former, from which it rapidly deposits on cooling. Casein, when dissolved by the assistance of the acids, is precipitated by the ferro-cyanide of potassium. It is distinguished from albumen, with which it possesses many physical and chemical properties in common, by being precipitated from solution on the addition of acetic acid, and the precipitate so formed being with difficulty soluble in an excess of the precipitant. It must not be imagined, however, that albumen under all circumstances cannot be precipitated from solution by the addition of acetic acid, for when dissolved in an alkaline solution, that proximate principle is immediately thrown down on the addition of the acid. Casein, like albumen, always contains some sulphur as a necessary element in its composition; the presence of this body may be easily shown by boiling casein in a concentrated solution of potassa, when the liquor rapidly assumes a brown colour, and gives out ammonia, an alkaline hydro-sulphuret remaining dissolved, which may be proved by the solution becoming of a deep black colour on the addition of a salt of lead. The aqueous solution of casein is precipitated by all the earthy and metallic salts which precipitate albumen in the dissolved state. Tannin precipitates it even from its solution in alcohol, notwithstanding that menstruum protects it from the precipitating action of the acids. The ultimate analysis of casein is, according to Thenard and Gay Lussac, carbon 59.781, nitrogen 21.381, hydrogen 7.429, and oxygen 11.409. Caseous matter, as precipitated by rennet in making cheese, is liable to a peculiar kind of putrefaction, which has been investigated by Proust and Braconnot; the latter obtained as a product of putrefaction a peculiar crystalline substance, to which he gave the name of aposepedine, from απο and σηπεδων, indicative of its origin. Proust had before noticed this substance and called it caseous oxide. It may be prepared very easily by allowing cheese to putrify under water and evaporating the solution so obtained to dryness; the dried mass is then to be treated with alcohol until that menstruum exerts no further solvent action; the portion insoluble in alcohol, on being dissolved in water, and digested with animal charcoal, yields us by filtration and evaporation pure crystals of aposepedine. This substance has the following properties: it is somewhat bitter to the taste, very slightly soluble in alcohol, soluble in water, and of greater specific gravity than that fluid. It sublimes when heated strongly, but always undergoes a partial decomposition. It contains sulphur. In addition to aposepedine, cheese when decomposing has been found to contain acetic acid, acetates of ammonia and potassa, chloride of potassium, ammoniaco-phosphate of soda, margarate and phosphate of lime, and a peculiar extractive matter.

I shall now proceed to consider the sugar of milk which is left in the whey after the separation of the cheese by rennet, and exists in solution with the salts of the milk, lactic acid, and animal extractive matter.

Sugar of milk may be obtained from whey by evaporating it to the consistence of a syrup, and setting it aside for a length of time, when small granular crystals of the principle are observed to deposit. The following are the principal qualities of sugar of milk. It has a sweetish taste, the grains crushing with difficulty between the teeth; its specific gravity is 1.543. It contains about 12 per cent. of water, which may be separated by carefully fusing it; when fused it is still quite white if the heat be not too strongly urged. It is soluble with difficulty in water, requiring three parts of boiling water and six of cold for that purpose. It is very slightly soluble in alcohol, and quite insoluble in ether. When acted on by concentrated nitric acid it becomes transformed into a mixture of oxalic, malic, and muric acids. By the action of caustic potassa it is changed to a brown-coloured bitter mass, which is insoluble in alcohol.

Sugar of milk has been stated to be incapable of undergoing the alcoholic fermentation; but late experiments by Hess (Poggendorff, Annalen der Physick) shew that such will occur, and an intoxicating liquor has been long known among the Tartars, which is prepared from the milk of the mare, and to which they give the name of Koumiss. Sugar of milk has been analysed by Berzelius: including its 12 per cent. of water, its composition is as follows:

Carbon....	40.125	or	1 atom,
Hydrogen..	6.762	or	2 atoms,
Oxygen....	53.113	or	1 atom:

or deducting the 12 per cent. of water,

Carbon....	45.94	or	5 atoms,
Hydrogen..	6 00	or	8 atoms,
Oxygen....	48.06	or	4 atoms.

It will be observed, on comparing the analysis of hydrous sugar of milk with that of starch, that they accord very nearly, and sugar of milk is convertible, as is the case with starch, into true sugar, by the action of sulphuric acid; these facts strongly point out the curious approach to vegetable matter which is made by this constituent of an animal secretion.

After the crystallization of the sugar of milk from the whey, we have left in solution, according to the experiments of Berzelius, lactic acid and lactates, chloride of potassium, an alkaline phosphate, phosphates of lime and magnesia, and traces of oxide of iron.

I shall not here enter upon the question whether or not lactic acid be the peculiar acid of milk, or whether the substance receiving that name be only a modification of the acetic; the matter is to be found noticed at length in the 7th volume of the French edition of Berzelius' Chemistry. For my own part I can only wish that one quarter of the animal acids mentioned in our modern chemical works had the same right to be distinguished as peculiar animal principles. Mons. Lassaigne, in his work bearing date 1836, when speaking of lactic acid, says, "regardé pendant long temps comme de l'acide acétique modifié par une matière organique, M. Berzelius a établi d'une manière incontestable sa véritable nature." Anhydrous lactic acid has the following ultimate composition.

Carbon................	50.50
Hydrogen	3.60
Oxygen	43.90

Berzelius' analysis of skimmed cow's milk is as follows:

Caseous matter with some butter	2.600
Sugar of milk................	3.500
Extractive, lactic acid, and lactates	0.600
Chloride of potassium	0.170
Alkaline phosphate....	0.025
Earthy phosphates, trace of oxide of iron..................	0.220
Water	92.875

The cream from this milk yielded the following result:

Butter..................	4.5
Caseous matter	3.5
Whey	92.0

The specific gravity of this milk was 1.0348, and that of the cream 1.0244.

A specimen of cow's milk which I lately examined was of sp. grav. 1.0338, and its solid contents 121.85 in 1000 parts.

The ashes of cow's milk, according to Pfaff and Schwartz, are composed of phosphates of lime, magnesia, and iron, phosphate of soda, chloride of potassium, and soda, which, before incineration, had existed in combination with lactic acid. They found 1000 parts of the milk yielded 3.742 parts of ash.

According to the experiments of Van Stiptrian, Luiscius, and Bondt, the proportion of cream which separates from cow's milk is about 4 per cent. of its weight. They obtained from milk 2.68 per cent. of butter, 8.95 of casein, and 3.60 per cent. of sugar of milk.

The first milk which is observed in the breast after parturition has received the name of colostrum; it differs somewhat from ordinary milk. It has been stated by some authorities that scarcely any cream can be obtained from the colostrum, and that no butter can be obtained by churning. According to Stiptrian, Luiscius, and Bondt, however, the colostrum from the cow yields 11.7 per cent. of cream, 3 of butter, and 18.75 of cheese. They state the specific gravity of the colostrum at 1.072; dried and incinerated it yielded $5\frac{1}{3}$ per cent. of ash. They do not mention sugar of milk as a constituent, and in this respect agree with MM. Chevallier and Henry, who do not mention it in their analysis of the colostrum of the cow.

Donné has observed a microscopic difference between the globules of the colostrum and those of milk. He states the colostrum globule to be made up of small granules united together, or enclosed in a transparent envelope. They disappear in ether, and when the fluid is evaporated, small tufts of acicular crystals are observed. Donné traced these globules in milk secreted twenty days after parturition. M. Güterbock has also observed these compound globules, and says he could detect the transparent membrane after the ether had dissolved the enclosed granules. M. Mandl has not been able to detect these compound globules, and believes them to be made up of agglomerated milk globules. The following is the result of a comparative analysis of colostrum and true milk by F. Simon.

	Colostrum.	Common milk.
Casein	4 per cent.	3.5 per cent.
Sugar	7 „	4.7 „
Butter	5 „	2.3 „

I shall now proceed to the consideration of the milk of the human subject, which differs in some respects from that obtained from the cow; its general characters are, however, identical. One of the principal differences to be observed consists in the caseous matter of human milk not being so universally precipitable by acids as that which exists in the secretion from the cow. Meggenhofen found but three out of fifteen specimens which he examined that could be precipitated by the hydrochloric or acetic acids. Three specimens of human milk examined by myself were found not to be precipitable either by the muriatic, nitric, or sulphuric acids. Although human milk resists the coagulating power of the acids, it is, notwithstanding, easily precipitable by rennet; but the curd so formed is some time in collecting, owing to the minute size of the precipitating flocculi; thus there appears both a physical and chemical difference between the caseous matter from the human subject and that from the cow. The casein of human milk being incapable of forming insoluble combinations with the mineral acids, may be regarded as bearing *chemically* the same relation to the casein of cow's milk that the albuminous matter of the chyle bears to that principle as it exists in the blood. The butyraceous matter of human milk has been stated by some chemists to be too liquid to admit of the formation of butter by churning; this, however, has been proved incorrect by the experiments of Pleischl, who succeeded in obtaining butter from the cream of human milk, which was similar in appearance to that from cow's milk, and experiments into the nature of this form of butter have been made by Meggenhofen, who considers it as identical with that obtained from the cow. The specific gravity of human milk has been stated so low as from 1.020 to 1.025, but this is certainly far too low; for out of six specimens which I examined the specific gravities varied between 1.030 and 1.035. The proportion of solid matter contained in milk is, according to Meggenhofen, 11 to 12.5 per cent. and sometimes more. I have had occasion to verify this result, having obtained 64.15 of solid matter from 500 grains of milk. The specific gravity of this specimen was, however, as high as 1.0358.

Human milk when fresh is either neutral or slightly alkaline. Its analysis, according to Meggenhofen, is as follows, being the results obtained from milk from three different subjects.

	No. 1.		
Alcoholic extractive, butter, lactic acid and lactates, chloride of sodium, traces of sugar of milk	9.13..	8.81..	17.12
Aqueous extractive, sugar of milk, and salts	1.14..	1.29..	0.88
Caseous matter (coagulated by rennet)	2.41..	1.47..	2.88
Water	87.25..	88.35..	78.93

The specific gravity of the milk appears to increase as the woman continues suckling, this increase ceasing at some period which is as yet undetermined. Milk at three days after parturition I found of specific gravity 1.0310, at four days 1.0334, and at six weeks 1.0358.

Payen has analysed three specimens of human milk with the following results:—

Butter	5.18..	5.16..	5.20
Caseous matter........	0.24..	0.18..	0.25
Residue of evaporated whey (containing the extractives, salts, and sugar of milk)	7.86..	7.62..	7.93
Water	85.80..	86.00..	85.50

Berzelius remarks upon these analysis, and says that a considerable portion of caseous matter remained in all probability in the whey, and was estimated in the residue obtained by evaporation.

According to Meggenhofen the salts contained in milk amounted to from 0.5 to 1.25 parts in 500 of the secretion. In an experiment made by myself, 500 grains of milk yielded 1.20 grains of salts.

Pfaff and Schwartz obtained 4.407 parts of ash from 1000 of milk, which they found to be composed as follows:—

Phosphate of lime..........	2.500
Phosphate of magnesia......	0.500
Phosphate of iron	0.007
Phosphate of soda	0.400
Chloride of potassium	0.700
Soda from decomposed lactate	0.300
	4.407

Berzelius very naturally expresses surprise that no carbonate of lime, chloride of sodium, or alkaline sulphate, is mentioned in this analysis, since casein always yields the earthy salt, and chloride of sodium is constantly present in animal matters which are intended for the nourishment of man. The absence of alkaline sulphate is quite inexplicable, as it is always a product of the combustion of animal substances containing an albuminous or caseous constituent. The proportion of cream contained in milk from the human subject has been determined by Sir Astley Cooper at from one-fifth to one-third by measure, varying with the health, the food, the habits, and state of mind of the mother. The colostrum or first milk which is observed in the human breasts has been examined by Meggenhofen. He states that it contains more saline matter than the after milk, and describes it as having the appearance of a weak solution of soap containing oleaginous particles. It is very prone to become sour and decompose, and becomes viscid by exposure to the air, hence its name from κολλωμαι, to agglutinate.

Several instances are on record of the existence of milk in the male breasts, and the analysis of a specimen lately published by Mayer in Schmidt's Jahrbucher, July 1837, is as follows:—

Fatty matter	1.234
Alcoholic extractive	3.583
Watery extractive	1.500
Insoluble matters	1.183
Total solid contents	7.500 in 100 parts of the fluid.

It was slightly alkaline. The following were the physical properties of this milk: when left at rest it quickly coagulated, and cream soon separated; after some hours butyraceous globules collected on the surface. Its specific gravity was 1024.

Milk from several of the herbivorous Mammalia has been examined by Stiptrian, Luiscius, and Bondt, with the following results:—

The milk of the ass has a specific gravity of 1.023 to 1.0355; it yields a white and light butter which is very apt to become rancid. The caseous matter does not separate so easily as in cow's milk; the whey, however, can be obtained very clear, and is found to contain more sugar of milk than that from the cow. An analysis yielded the following result:

Cream	2.9 per cent.
Casein	2.3 „
Sugar of milk	4.5 „

The milk of the mare has a specific gravity of 1.0346 to 1.015; it yields but little cream, but contains a very large proportion of sugar; the analysis gave:

0.8 per cent. of cream,
1.61 „ caseous matter,
and 8.75 „ of sugar of milk.

The milk of the mare, as also that obtained from the ass, very rapidly commences the alcoholic fermentation, an effect which cannot be produced but with the greatest difficulty in cow's milk.

Goat's milk has a specific gravity of 1.036; it possesses a very disagreeable odour of the animal, and the more strongly so if the goat be dark-coloured; it yields a large quantity of cream and butter; the latter contains, in addition to the usual acids of butter, a peculiar acid to which the name of hircic acid has been given; it is to this principle that goat's milk owes its peculiar unpleasant odour. This milk contains also a large quantity of caseous matter of a firm dense character. Payen found goat's milk composed as follows:

Butter	4.08
Casein	4.52
Sugar, salts, and extractives ..	5.86
Water	85.50

Stiptrian, Luiscius, and Bondt procured 7.5 per cent. of cream, 4.56 of butter, 9.12 casein, and 4.38 per cent. of sugar from the milk of a goat.

The milk of the sheep has a specific gravity of 1.035 to 1.041; it yields a larger proportion of cream: the butter is semifluid and pale yellow in colour; it putrifies very easily. This milk yields 11.5 per cent. of cream, 5.8 of butter, 15.3 of caseous matter, and 4.2 per cent. of sugar of milk.

The milk of the bitch and also of the porpoise have been lately examined by Dr. Bird; the former contained 15.8 per cent. of casein, and 7.2 of butter mixed with some sugar of milk. That from the porpoise contained 23.00 per cent. of oily matter, and a volatile ingredient supposed to be phocenic acid. The specific gravity of bitch's milk is stated at 1.024.

The milk is very prone to become contaminated by various ingesta; that of the cow is frequently impregnated by the odours derived from particular pasturage, and if saffron or indigo be mixed with their diet the milk has been observed to assume more or less the colour of those pigments.

Chevallier, Henry, and Peligot made experiments on the milk of asses to whom several different substances had been exhibited; they were enabled to detect the oxides of iron and zinc, the trisnitrate of bismuth, common salt, and sesquicarbonate of soda with great ease; sulphate of soda required to be administered in very large doses before it could be detected in the milk, and sulphate of quinine could not be discovered, though large quantities were introduced into the stomach. These gentlemen state likewise that the iodide of potassium cannot be detected in the milk unless exhibited in doses of upwards of a drachm. This rule, however, cannot apply to the human subject, as I lately very readily detected it in the milk of two of my patients, one of whom had taken only 45 grains of the iodide in divided doses of 5 grains each, administered three times a day for three days; and the other 105 grains in 21 doses of 5 grains each, administered in like manner. It is probable that many substances enter the milk which the present state of chemistry does not admit of our detecting, and every practitioner is aware of the danger incurred to the child by exhibiting any active medicine to the mother during the period of lactation.

There is perhaps no animal secretion which bears so strongly-marked an analogy with the blood as the milk, and which promises us so fair a prospect of discovery in the mysteries of secretion, and we cannot but hope that as animal chemistry advances we may be able to imitate those changes which occur in the minute parts of the mammary gland, where, though each constituent of the blood be changed in its character to form milk, yet each constituent of that secretion retains an obvious type in the fluid from which it was eliminated; thus if we compare the blood and this secretion side by side, we remark not only identical physical changes to occur, but also the existence of a set of proximate elements, which, though proper to each, still possess many chemical qualities in common; for instance—

Blood separating into			Milk separating into
Clot	Fibrin	Casein	Cream
	Red particles	Butyraceous matter	
and			and
Serum	Albumen	Casein	Milk or skim milk
	Alcoholic extractive, viz. lactates	Alcoholic extractive, viz. lactates and lactic acid	
	Aqueous extractive; albuminate of soda	Aqueous extractive, with sugar of milk	
	Alkaline salts	Alkaline salts	
	Fatty matter	Fatty matter	

The similarity of reaction between fibrin, albumen, and casein is well known to chemists, and the derivation of the latter from the former can scarcely admit of a doubt; the only difference acknowledged between fibrin and albumen is a physical one, and it would be exceedingly interesting to ascertain whether or not the casein, which, like fibrin, separates on standing, be not physically different from that portion of casein which remains in the fluid after the milk has creamed. The red particles of the blood certainly bear no analogy whatever to the butyraceous matter of milk in its perfectly formed state; it is a curious fact, however, noticed by Sir Astley Cooper, that the colostrum at its first appearance is occasionally of a red colour, and the cream which separates is of a still deeper red tinge, thus rendering it probable that the fatty matters are in this instance the colouring ingredient. I may mention, in addition, that it is not easy to obtain hæmatosine quite free from fatty matter; there appears to exist a natural affinity between them.

The alcoholic extractives of blood and milk are too obviously analogous to need comment, as are the salts and likewise the fatty matters adherent to the casein of the milk and the albumen of the serum. The sugar of milk appears in all probability derived from the aqueous extractive of the blood, an ingredient which has scarcely attracted sufficient attention, and the development of whose chemical relations may perhaps assist us greatly in obtaining a further insight into the true nature of those changes which are effected in the minute structure of secreting glands. I have thought it right to mention the above resemblance, as I cannot help thinking that we may be greatly assisted hereafter in the physiology of secretion by attempting to reduce each proximate element of a secerned fluid to some type in the blood, and afterwards endeavouring artificially to produce those substances from their analogues in the circulating fluid; as nature may perhaps in this way form them for the various secretions, by the so-called chemistry of vitality. Physiologists and chemists are, in the present day, too prone to attribute the formation of those substances contained in secretions, and which cannot be detected in the blood, to changes occurring among the ultimate elements of organic matter, changes of a character too intimate and obscure ever to be induced by those reagents which non-vital chemistry applies in effecting transformations. Such a conclusion is founded on the assumption that organic chemistry is not to make that progress which we now see in almost every branch of inquiry, a progress marked by the development of new laws which not only become valuable as indicators for the ascertainment of new facts, but which have a retrospective influence on science, rearranging and altering the bearings and relations of previously ascertained phenomena.

(G. O. Rees.)

MOLLUSCA, (Lat. *mollis,*) *Malakia* and *Ostracoderma* of Aristotle; *Mollusques,* Fr.; *Weichthiere, Mollusken,* Germ.; *Mollusks,* Engl.; invertebrated animals, distinguished by Bruguiere from insects by the negative characters of the absence of bones, of stigmata, and of jointed feet; and first accurately defined by Cuvier as a primary division of the animal kingdom, with the following anatomical characters. The Mollusks are animals without an articulated skeleton or a vertebral column. Their nervous system is not concentrated in a spinal marrow, but merely in a certain number of medullary masses dispersed in different points of the body, the chief of which, termed the brain, is situated transversely above the œsophagus, and encompasses it with a nervous collar. Their organs of motion and of the sensations have not the same uniformity as to number and position as in the Vertebrata, and the irregularity is still more striking in the viscera, particularly as respects the position of the heart and respiratory organs, and even as regards the structure of the latter: for some of these respire elastic air, and others water, either fresh or of the sea. Their external organs, however, and those of locomotion are generally arranged symmetrically on the two sides of an axis. The circulation of the Mollusks is always double; that is, their pulmonary circulation describes a separate and distinct circle. The blood of the Mollusks is white or bluish, and it appears to contain a smaller proportionate quantity of fibrine than that of the Vertebrata. The veins probably fulfil the functions of absorbent vessels. Their muscles are attached to various points of their skin, forming more or less dense and complex tissues. Their motions consist of various contractions, which produce inflections and prolongations of their different parts, or a relaxation of the same, by means of which they creep, swim, and seize upon various objects, just as the form of these parts may permit, but as the limbs are not supported by articulated and solid levers they cannot advance rapidly. Nearly all Mollusks have the body enveloped by a duplicature of soft and usually muscular integument, which bears more or less resemblance to a *mantle:* it is sometimes narrowed into a simple disc, sometimes prolonged into one or more tubes, or is extended and divided in the form of fins.

The *Naked Mollusks* are those in which the mantle is simply membranous or fleshy. In most of the species one or more plates, of a substance more or less hard, are developed in its substance, usually in successive layers, which increase in extent as well as in thickness as they are successively formed. When this substance remains concealed in the thickness of the mantle, it is still customary to style the animals 'Naked Mollusks.' Most commonly, however, it becomes so much developed that the contracted animal finds shelter beneath or within it, and it is then termed a *shell*, and the animal is called a *Testaceous Mollusk*.

The mode of generation is too varied in the Mollusks to afford any common character to this sub-kingdom: but, being for the most part sluggish and feeble animals, with low and little varied instincts, they are preserved chiefly by their fecundity and vital tenacity.

The nervous system of the Mollusks may consist of one or more ganglionic masses; but these are scattered, often irregularly or unsymmetrically, through the body, and the intercommunicating chords never form a symmetrical knotted pair along the middle line of the ventral surface of the body; whence the term '*Heterogangliata*,' expressive of the characteristic condition of the nervous system, with which the unshapely and often unsymmetrical figure of the whole body corresponds.

The number of the ganglia follows closely the progressive development of the muscular system: the first is that which is found between the anal and respiratory tubes of the Ascidiæ, and which regulates the elongator and sphincter muscles of these tubes. The development of a muscular heart and of a bivalve shell with its adductor muscle is accompanied with the appearance of a second ganglion or centre of the nerves which supply that muscle: a second adductor muscle, with the superaddition of a muscular foot and its retractors, produces an additional ganglion or ganglions, and the complication of the nervous system is further augmented when the breathing and anal siphons are unusually prolonged, and provided with strongly developed annular contractile muscles and with proportionately powerful retractors. The progressive development of the nervous system may be traced thus far in the tunicated and bivalve Mollusca without its reaching the stage which is marked by the appearance of a distinct supra-œsophageal ganglion or brain: the species have, in fact, no distinct head, and are termed *Acephalous Mollusks*. The first appearance of this important part with its appendages, which are usually subservient to the organs of special sense, is associated with an accumulation of nervous matter, in the form of a transverse chord, with a ganglion or ganglions, above the commencement of the œsophagus, forming the brain; whence these Mollusks are termed '*Encephalous*.'

The development of the brain proceeds directly as the organs of the senses increase in number and complication, and consequently reaches its maximum in the higher Cephalopods with highly complex eyes and distinct organs of hearing; and in these the brain is protected by a cartilaginous cranium, forming the first representative of the true internal skeleton which is met with in the Invertebrate division of animals, and one of the main organic characters by which the higher Mollusks surpass Articulates in the ascent to the Vertebrate type.

The nervous system of the Mollusks is remarkable for the peculiar and distinct colour of the ganglions in certain species, as the freshwater Muscles and Unios; and for the contrast between the density of the cellular sheath of the nerves and the semifluid pulp which it contains. This structure allows of an artificial injection of the nerves, which has led some anatomists to describe them as parts of an absorbent system.

Although the bivalve Mollusks are headless and without brain, some of them have manifested signs of a perception of light, and in a few species simple ocelli have been detected on the verge of the mantle.

In the Encephalous Mollusks the eyes, when present, are small, never exceed two in number, and are usually supported on flexible peduncles or tentacula; but in the Dibranchiate Cephalopods they are large, always sessile, and highly complicated.

The organ of hearing is peculiar to the Cephalopods in the present division of the animal kingdom.

The organ of smell, as a special and circumscribed part, has likewise been recognized only in the highest class: but Cuvier observes, that the skin of the Mollusks so clearly resembles in its softness and lubricity a pituitary membrane, that they probably may recognize odours at every point of their external surface. Professor De Blainville conjectures that in the Gastropods the soft extremities of the first pair of cephalic tentacles may be the seat of the organ of smell. An organ of taste has of course been recognized only in the Encephalous Mollusks, in many of which the tongue is large and complex, and in the Cephalopods is evidently provided with gustatory papillæ. The sense of touch is in this as in other groups of animals the most generally possessed and the most widely diffused over the body. The marginal fringe of tentacles on the mantle of most Bivalves; the branched processes of the skin in certain Pteropods and Gastropods; the cephalic tentacles or 'horns,' as they are termed, in the Snail and allied Mollusks; the rich and varied apparatus of cephalic and labial tentacles—nearly one hundred in number—in the Nautilus; and the extremities of the acetabuliferous arms of the higher Cephalopods, may all be regarded as organs of delicate sensation: the same opinion may reasonably be entertained of the highly vascular surface of the ventral locomotive disc or 'foot' in the Slug, Snail, and other Gastropods.

The voluntary muscular fibre of the Molluscous animals is distinguished from that of the Articulate and Vertebrate animals by the absence of the transverse striæ, and in most of the Acephalous Mollusks it is antagonized by a merely elastic gelatinous fibre. In the Tunicaries the flexible outer coat obeys and opposes the change of form which the inner muscular envelope occasions. In the Bivalves, whose shell affords firm levers of attachment to the muscles, the antagonizing elastic force is implanted at the hinge of the shell; and some of the species (*Mollusca subsilentia* of Poli) can, by virtue of this mechanism of solid lever with its attached muscular and elastic fibre, execute short leaps.

The Encephalous Mollusks with a cerebral centre of nervous influence antagonize one series of muscles by the regulated action of another series, and are no longer dependent on mere elastic fibres for their movements. The musculo-cutaneous mantle is produced in the form of fins in the Pteropods, Heteropods, and some Cephalopods; or there is an accumulation of longitudinal fibres, intersected by oblique or transverse ones on the ventral surface of the mantle, producing the thick contractile disc, which is termed the foot. This sometimes extends the whole length of the body, as in the Gastropods, sometimes is developed only from the region of the neck, as in the Trachelipods. The attachment of the body to the shell in these Mollusks, the presence of, and power of retracting and elongating, a siphon or breathing tube, the movements of the head and its appendages, especially when these are developed into instruments of progressive motion and prehension, as in the Cephalopods, are the chief conditions of the progressive advancement and complication of the muscular system in the Molluscous sub-kingdom.

The heterogangliate type of the nervous system, with the correspondingly low condition of the muscular and other organs of relation, which, commencing in the Ciliobrachiate Polypes, is established in the Mollusks, is on the whole very inferior to the conditions and powers of the sensitive and motive systems in the Articulates: but, on the other hand, "the organs of growth and reproduction become more evolved; and in the *Mollusca* we are presented with a perfecting of the internal organs, which is to prepare for and to be more fully developed in the higher animals."*

The alimentary canal is provided with a separate mouth and vent: the stomach may be distinguished from the œsophagus and intestine, and a liver is present in all the Mollusks, and is remarkable in most for its large size and complicated lobular form. The bile is secreted from arterial blood. The mouth in the Acephalous Mollusks is generally concealed in the interior of the pallial cavity, but is always situated at the anterior part of the body, or that which is opposite to the excrementory and respiratory tubes or orifices. There are neither jaws nor salivary glands in this division. Among the Encephala, however, in which the mouth is armed with horny plates representing in different species the knife, the saw, the rasp, or the scissors, the salivary system attains an extraordinary degree of development, especially in the Cephalopods, in which the mandibles resemble those of the Raptorial bird, and sometimes have their margins armed with a calcareous dentated plate. In the Cephalopods the pancreas makes its first appearance. The special forms of the progressive complications of the digestive system in the present division of animals will be found amply illustated in the articles TUNICATA, CONCHIFERA, PTEROPODA, GASTROPODA, CEPHALOPODA.

The circulating system, which, as has been stated, is complete and double in all the Mollusks, is provided in all the species with a systemic heart, and in the highest organized species with a distinct heart for the lesser or branchial circulation. The systemic heart first appears in the sessile Tunicaries as a vasiform undivided ventricle, which, however, is inclosed in a distinct pericardium. It is concentrated into a more compact muscular organ in the Conchifers, and divided into a venous and arterial chamber; but the auricle, and sometimes also the ventricle, as in *Arca*, is subdivided and segregated, according to the law of self-repetition, which is exemplified in all the systems of organs at their first appearance in the animal kingdom. The heart of the Gastropods exhibits the higher type of a single auricle and ventricle, both placed at the termination of the lesser and the commencement of the greater circulation. In the highest Cephalopods the course of the blood is accelerated in both circulations by a muscular ventricle, but the superadded analogue of the pulmonic heart here, likewise, at its first appearance illustrates, by its separation into two distinct ventricles, the law above alluded to in reference to the systemic heart of the lower Mollusks.

The respiratory organ is distinctly developed in all Mollusks, and is subject to the greatest variety of forms in this division of the animal kingdom; yet, with the exception of the small sessile order of Ascidians at the lowest extreme,

* See the eloquent and philosophic 'Recapitulary Lecture' of Prof. Green, Vital Dynamics, 8vo. 1840.

connecting the Mollusks with the Zoophytes, it affords perhaps the best positive character of this great primary group of the animal kingdom; for whereas, in the Articulate division, the breathing organs are lateral or open upon or towards the sides of the body, and in the Vertebrate division communicate with the oral extremity of the nutritive canal, in the Mollusca they are connected with the anal outlet.

The uropoietic system, where traces of it are recognizable, as in most Gastropods and in Cephalopods, likewise communicates with the respiratory cavity.

The rich endowment of vibratile cilia deserves to be noticed as characterizing the branchial organs, and constituting the chief mechanism of respiration in most Mollusca. The organs of vegetative life subservient to the procreation of the species are not less remarkable for bulk, variety, and complexity than are those which minister to the preservation and growth of the individual. Although comparatively simple and reduced to the essential formative organs in the Acephala, they are, with very few exceptions, placed in distinct individuals, that is to say, one Ascidian or Oyster possesses only the testicle, and is a male; another only the ovarium, and is a female. In the order Conchifera, the females have the gills modified to serve as a receptacle for the impregnated ova during fœtal development.

Among the Encephalous Mollusks are many hermaphroditical species, some with the male and female organs terminating sufficiently close together for independent or self-impregnation; others having the outlets of the two organs remote, and requiring the concourse of another individual in reciprocal fecundation; or the same individual is impregnated by another and impregnates a third, as is curiously exemplified in the nuptial chain thus formed by numerous individuals of the Marsh-snails (*Lymnæa*). The Trachelipods and Cephalopods are again diœcious, like the lowest classes of Mollusks, but exhibit the generative organs under the highest stage of complication; and some of the latter class are remarkable for the expulsion not only of the ova aggregated in groups contained in special receptacles, but also of the spermatozoa in a similar state of aggregation in cylindrical cases, which, by the arrangement of their elastic tissue, manifest movements, prior to their rupture, which have long excited the surprise and admiration of the physiological observer.

A large vitellus, among the numerous nucleated cells of which it is often difficult to recognize a single one as the centre of development, or as the germinal vesicle, characterizes the ovum of most Mollusks. In most species also the early formation of vibratile cilia on the surface of the germinal membrane, and the rotation of the embryo upon its axis produced by their action, are striking though not peculiar phenomena. The adherence to a uniform type in the earlier periods of growth is singularly manifested in the young of Tritonia, Doris, Aplysia, and other naked Mollusks, which are protected for a certain period by an external spiral univalve shell.

The classification of the Molluscous animals has exercised the judgment and discrimination of some of the ablest Zoologists, and is a subject too expanded for the limits assigned to the present article. The principles of a natural distribution into the larger groups according to general organization seem to be adhered to in the following system.

Taking the nervous system as a guide to the divisions of highest value and extent, the Mollusca separate themselves, as already shown, into ACEPHALA and ENCEPHALA.

The Acephala may be divided according to the nature of their external covering into TUNICATA, where this is continuous, flexible, and elastic; and into CONCHIFERA, where it is testaceous and divided into two or more valves. The Conchifera may be subdivided according to the modifications of the respiratory organs into *Palliobranchians* and *Lamellibranchians.* Respiratory characters likewise mainly distinguish the sessile Tunicaries or *Ascidians,* and the floating Tunicaries, or *Salpaceans.*

The Encephalous Mollusks are classified according to their organs of locomotion, as PTEROPODS, GASTROPODS, and CEPHALOPODS. The respiratory organs afford the best characters for the subdivisions or orders of these three classes.

(*Richard Owen.*)

MONOTREMATA, Gr. *μονος, single, τρημα, hole,* in reference to the single cloacal excrementory and generative outlet; Fr. *Monotrèmes;* Ger. *Monotremen;* Eng. *Monotremes.*

An order or primary group of the Implacental subclass of MAMMALIA, representing the *Edentata* in that subclass; allied to the *Marsupialia* by the absence of the corpus callosum and by the presence of the marsupial bones, but differing in the absence of the abdominal pouch and scrotum, in the absence of teeth, in the simplicity of the bigeminal bodies, and in some remarkable modifications of the skeleton and generative organs.

As the order *Bruta* or *Edentata* is that which exhibits the lowest modifications of the Placental type of the Mammalian structure, and offers in some respects the nearest approach in that subclass to the Ovipara, so the *Monotremata* present the extreme modifications of the Implacental type, and make the last step in the transition from the Mammalian to the Oviparous classes.

The Monotremes are, however, true Mammalia in all essential points of structure: they possess functional mammary glands, which are largely developed at the breeding season: their lungs consist of a spongy tissue, subdivided throughout into very minute cells; they are suspended freely in a thoracic cavity, separated by a complete muscular and aponeurotic diaphragm from the abdomen: the arch of the aorta bends over the left bronchus: the larynx is superior, and is defended by a well-developed epiglottis: the kidneys are compact conglobate glands with distinct cortical and medullary substances, secreting the urine from arterial blood, and returning the blood to the cava by a single large vein. The lower jaw articulates with the base of the zygomatic, and not with the tympanic element of the temporal bone, and the cranium articulates by two distinct condyles with the atlas.

The quadrupeds which combine these essential mammalian characters with the oviparous modifications above-mentioned are peculiar to Australia and Van Dieman's Land; they form three well-marked species, referable to two distinct genera. One of these genera, called *Echidna* by Cuvier, is characterized by an elongated slender muzzle, terminated by a small mouth, and containing a long and extensible tongue like that of the Ant-eaters. The jaws are edentulous, but the palate is provided with many rows of small, sharp, hard, epidermal spines, which are directed backwards, and the base of the tongue is similarly armed. The feet are short, but remarkably broad and strong, and are each provided with five very long and strong claws. The upper part and sides of the body are defended by spines similar to but larger than those of the hedge-hog. The tail is very short. The genus *Echidna* contains two species, one *(Ech. hystrix)* characterized by a more complete armour of spines, with a scantier admixture of darker coloured hair; the other *(Ech. setosa)*, by being clothed with a greater proportion of lighter coloured hair, which half conceals the spines. These characters are constant in both sexes, and as well marked in the mature as in the young individuals.

Both species of Echidna are terrestrial and fossorial; they feed almost exclusively on ants, and abound in certain districts of both Australia and Tasmania, playing there the same part in the economy of Nature which is assigned to the Pangolins *(Manis)* in Asia and Africa, and to the Ant-eaters *(Myrmecophaga)* in South America.

The *Ornithorhynchus*—the second genus of the Monotrematous order—is an aquatic Insectivore,* but combines water-snails, worms, and other small Invertebrata with the insects that constitute the staple article of its food. These it obtains, not by its tongue, which is short and inextensible, but by its lips, which are largely developed, and supported by singularly modified intermaxillary and lower maxillary bones; the whole mouth presenting a close resemblance to the broad and flattened beak of a duck. The similarity is increased by the lateral lamellæ of the lower jaw; but both jaws are provided with four horny teeth; the anterior one on each side, both above and below, is long, narrow, and trenchant; the posterior one is broad, flat, and shaped like a molar tooth. The feet are short, broad, armed each with five claws, but less robust than in the Echidna. The fore feet have a web, which not only unites and fills the interspaces of the toes, but extends beyond the extremities of the claws; the web of the hind foot terminates at the base of the claws. With these swimming-feet is associated a strong, broad, horizontally flattened tail, which completes the organic locomotive machinery for the aquatic existence of an air-breathing and warm-blooded quadruped. The body is clothed with a dense coat of hair, which consists of a fine fur, intermixed with long, stiff, flattened, and sharp-pointed hairs, that seem to represent the spines of the Echidna. Only one species of *Ornithorhynchus* is as yet satisfactorily defined; it occurs in the fresh-water rivers, ponds, and lakes of Australia and Van Dieman's Land.

As external ears and large eyes would be ill suited to the habits either of a burrowing or a swimming animal, both genera of Monotremes are characterized by the absence of the auricle and the small size of the visual organs. The male in both genera bears a horny pointed spur upon the heel, which is perforated, and transmits into the wound it inflicts the secretion of a peculiar gland. This singular repetition of an offensive mechanism, which, prior to the discovery of the monotrematous mammals, was known only in certain insects and serpents, completes the anomalous combinations in the external characters of the present order.

Echidna hystrix and *Ornithorhynchus paradoxus* were first described and figured by Dr. Shaw; the former as early as the year 1792 in the third volume of the Naturalists' Miscellany, under the denomination of *Myrmecophaga aculeata;* the latter in the tenth volume of the same work in the year 1799, by the name of *Platypus anatinus*.

In the following year this more extraordinary animal received a further description, together with its present zoological denomination from Professor Blumenbach, in " Voigt's Magazin für den neuesten Zustand der Naturkunde, Bd. ii, 1800;" and soon after Sir Everard Home gave an account of some of its anatomical peculiarities, which appeared in the Philosophical Transactions for the year 1800. As these observations, however, were limited to the head and beak, they rather tended to perplex than guide the naturalist in assigning the position of the animal in the natural system.

Professor Blumenbach, in his Elements of Natural History, placed the *Ornithorhynchus paradoxus* among the *Palmata* of his mammalogical system, between the otter and the walruss; while Dr. Shaw more naturally referred it to the *Bruta* of Linnæus; but being limited to such points of comparison as the external form alone presented, he merely discerned the affinities of the *Platypus* and the *Echidna* to the *Myrmecophagæ*. The real value and extent of these affinities could only be determined by a deeper insight into their respective organizations. The important memoirs on the anatomical structure of both these animals read before the Royal Society by Sir Everard Home, and published in the Philosophical Transactions for 1802, drew the attention of the scientific

* See No. 541, B. Physiological Series, Museum Royal College of Surgeons, London. " Debris of Insects belonging to a genus of the *Nauceridæ*, which were found in the cheek-pouches of the *Ornithorhynchus paradoxus*." Mr. Bennett (Zool. Trans. 1834, p. 239) found in the cheek-pouches of the Ornithorhynchus mud and gravel, with fragments of insects and shell-fish.

world more strongly towards their remarkable peculiarities and deviations from the ordinary structure of the Mammalia. In these investigations the author having brought to light numerous instances of mutual affinity, before concealed under very dissimilar exteriors, grouped the two animals together under the same generic appellation, adopting that of *Ornithorhynchus*, proposed by Blumenbach. He likewise expressed his opinion that they differed considerably in their mode of generation from the true Mammalia, on the ground of the peculiarities of the organs themselves, and on the absence of nipples in both species, and especially in the female of the *Ornithorhynchus paradoxus*.

The opinion of Sir Everard Home was soon after adopted by Professor Geoffroy St. Hilaire, who, in the *Bulletin des Sciences Philomathiques*, (tom. iii.), constituted a new order for these animals under the term 'Monotremata;' having been led to believe, from an imperfect dissection, that the genital products of both sexes as well as the urine and excrement, were voided by a single common outlet. Concluding, also, by inference that the mammary glands as well as nipples were wanting, and strengthened in his belief of the oviparous nature of the Monotremata by some accounts from New South Wales respecting the discovery of the eggs of the Ornithorhynchus,* he subsequently separated the Monotremata altogether from the Mammalia, and characterized them as a class intermediate to Mammalia, Birds, and Reptiles.

This mode of viewing the Monotremata was not, however, generally assented to. The Baron Cuvier, who in one of his earliest works * had separated the *Myrmecophaga aculeata* of Shaw from the true Anteaters under the generic term '*Echidna*,' and who afterwards made considerable additions to its anatomical history, as well as to that of the *Ornithorhynchus paradoxus*, in the *Leçons d'Anatomie Comparée*, whilst he adopted the collective term 'Monotremata,' admitted it in the '*Regne Animal*' as indicative only of a tribe or family in his order *Edentata*. Spix, Oken, and De Blainville more decidedly opposed the opinion of Geoffroy, and the latter naturalist in an express dissertation on the place which the Ornithorhynchus and Echidna ought to hold in the animal kingdom, after adducing the numerous instances in which the structure of the Monotremes agrees with that of the true Mammals, expresses his opinion that the mammary organs will ultimately be detected, and considers the animals themselves as most closely allied to the Marsupial order.

The exact position of the Monotremata, their natural affinities, and the value of the group, could, however, be only a matter of speculation before their organization, and especially their cerebral structure, had been thoroughly elucidated; the consideration of these points will therefore be resumed after the requisite anatomical and physiological details have been given, for a knowledge of which, as regards the Ornithorhynchus, science is chiefly indebted to the celebrated Meckel.†

Skeleton of the Echidna Hystrix. (Pander and D'Alton, corrected from Nature.)

OSTEOLOGY.

Of the skull.—The skull in both genera of Monotremata is long and depressed, but is characterized by a relatively larger cranium in proportion to the face than in the Marsupials. The parietes of the expanded cerebral cavity are rounded, and their outer surface is smooth. These characters are most conspicuous in the Echidna, in which the jaws are slender, elongated, and gradually diminish forwards to an obtuse point, so that the whole skull resembles the half of a pear split lengthwise. The facial angle of the Echidna is 36°, that of the Ornithorhynchus 20°, being almost the lowest in the mammiferous class. The cranial bones and their constituent pieces continue longer distinct in the Echidna than in the Ornithorhynchus; and their relative position, their con-

† See his beautiful Monograph, "Ornithorhynchi Paradoxi Descriptio Anatomica," folio, 1826.

nections, and the proportions in which they enter into the formation of the skull, have been in great measure determined and described in that genus.*

I have had the opportunity of investigating the composition of the cranium, a point so important in regard to the natural affinities of the Monotremata, in the young Ornithorhynchi transmitted to the Zoological Society of London by Dr. Weatherhead; and the comparison of this part of their anatomy has enabled me better to appreciate and understand peculiarities of the same part in the Echidna, the skull of which is here also described from original specimens.

In the cranium of a young but full-grown specimen of *Echidna setosa*, (*g*, *fig*. 169, 170, 171,) the four elements of the *occipital bone* are unanchylosed and are joined together by smooth linear harmoniæ. The basi-occipital (*fig*. 170, *a*) presents a six-sided rhomboidal figure, with the posterior margin notched to complete the lower boundary of the large vertical occipital foramen, and thickened and smoothly rounded to form the inferior extremities of the two occipital condyles. These condyles are principally developed from the ex-occipital elements (*figs*. 169, 171, *b*, *b*), which are expanded superiorly and terminate in an angle wedged in between the supra-occipital and petrous bones; they extend, but do not meet, above the occipital foramen, being separated by a notch closed by membrane in the recent state. The supra-occipital element (*figs*. 169 & 171, *c*) is a transversely oblong quadrilateral plate of bone; its short lateral margin is joined by a linear harmonia with the upper part of the os petrosum, on each side; the wide anterior margin is similarly articulated with the single parietal bone, and is slightly overlapped by its posterior margin; this representative of the deltoid suture runs straight across the posterior and upper part of the skull.

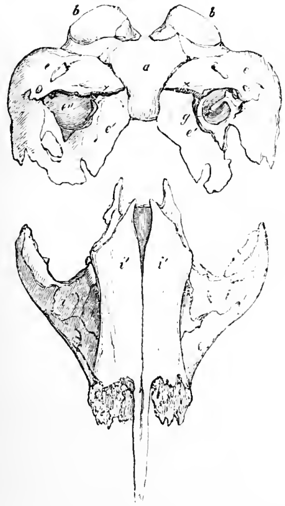
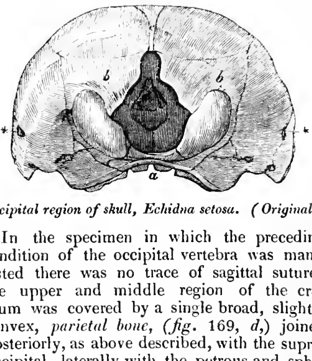
Skull of Echidna setosa. (Original.)

Fig. 170.



Occipital and sphenoidal cranial vertebræ, Echidna setosa. (Original.)

Fig. 171.



Occipital region of skull, Echidna setosa. (Original.)

In the specimen in which the preceding condition of the occipital vertebra was manifested there was no trace of sagittal suture; the upper and middle region of the cranium was covered by a single broad, slightly convex, *parietal bone*, (*fig*. 169, *d*,) joined posteriorly, as above described, with the supra-occipital, laterally with the petrous and sphenoid bones, and anteriorly with the sphenoid and frontal bones, which the parietal overlaps

* See Leçons d'Anatomie Comparée, Ed. 1837.

by a squamous modification of the coronal suture. The part described in this Article as a lamelliform portion of the petrous bone, (*fig.* 169, *e*,) which extends upon the lateral and part of the posterior region of the skull, is regarded by the Editors* of the Leçons d'Anatomie Comparée, Ed. 1837, as the squamous portion of the temporal; and the flat oblong bone, (*fig.* 169, B,) which forms part of the lateral wall of the cranial cavity and the posterior half of the zygomatic arch, and which supports the articular surface for the lower jaw, is thought to be the malar bone. But when we consider the low development or total disappearance of the malar bone in the skull of the *Insectivora* generally, as in *Echinops* and *Centetes* among the *Feræ*, and as in the edentate *Manis* and *Myrmecophaga*, it is unlikely that the malar bone should attain so superior a size and fulfil such important functions in the Monotrematous Edentata, in which its condition, according to the above views of the editors of the Leçons d'Anat. Comparée, would be unique in the mammiferous class. It appears to me to be more reasonable to regard the malar bone as either altogether absent in the Echidna, as it is in the Manis, and the zygomatic arch as being completed in the Echidna by a greater extension of the zygomatic processes of the temporal and superior maxillary bones; or else to suppose that these are actually united, at an earlier period, by a separate intervening jugal style, which, however, I have not been more successful in finding than the Continuators of Cuvier. With respect to the great development which the petrous bone, according to my view, must present in the Echidna, it may be observed that this bone forms part of the occipital region of the skull in most Marsupials, and also contributes as large a proportion to the lateral parietes of the skull in certain Rodents, as the *Helamys*, as it is here described to do in the Echidna.

The side of the cranium is principally formed by the largely developed *petrous bone* (*fig.* 170, *e*) and the great ala of the *sphenoid*, which meet and are joined in the interspace separating the parietal from the squamo-temporal bone, by a nearly vertical harmonia half an inch long; this harmonia is crossed at nearly right angles by a deep groove, which in some parts sinks through the wall of the cranium and exposes its cavity. The groove or canal first runs between the squamous and petrous elements of the temporal bone, and is a conspicuous feature in the skull of the Ornithorhynchus.

The lower part of the side of the skull of the Echidna is closed by the *squamous element of the temporal*, which overlaps a large portion of the petrous bone, and by a small portion of the sphenoid: it is represented detached from the skull at *fig.* 169, B. The lower boundary of the squamo-temporal forms a straight line, from which the glenoid surface for the lower jaw (*f*) is extended inwards at a right angle, upon the base of the skull; the anterior part is continued forwards, protecting the temporal fossa by a thin vertical plate of bone, and then diminishes to a slender, straight, styliform, zygomatic process which rests obliquely on a corresponding process of the superior maxillary bone.

The tympanic cavity is shallow, and excavated in the basal part of the petrous bone, where it is widely open in the macerated skull: it is figured closed by the tympanic bone and membrane at *g*, *fig.* 170, and exposed by their removal at *e''* *fig.* 170. The plane of the membrana tympani is horizontal, and its external surface looks nearly downwards. Three-fourths of its circumference are implanted in the groove of the very slender incomplete hoop formed by the detached tympanic bone, which is figured with the anchylosed malleus at c, *fig.* 169. The petrous bone is continued from the tympanic fossa forwards and inwards, in the form of a broad and nearly horizontal process, (*fig.* 170, *e'*,) to the pterygoid plate of the sphenoid, (*i'*, *i'*,) which is also horizontal. The petrous and pterygoid plates are joined by an oblique harmonia, and both contribute to extend the bony palate backwards. The palatal process of the petrous bone is abruptly terminated behind by the Eustachian groove (*fig.* 170*).

The frontal bone (*fig.* 169, *h*) in the cranium here described was divided by a median frontal suture, toothless like the rest; the angle between the superior and the orbital plates is rounded off; the orbital plate joins the great ala of the sphenoid by a deeply sinuous suture. The anterior part of the frontal is largely overlapped by the bases of the nasal bones, which encroach upon the interorbital space.

The *nasal bones* (*fig.* 169, *n*) receive the upper edge of the superior maxillary bone into a groove at their outer margin, and articulate anteriorly with the *intermaxillaries* (*fig.* 169, *o*); but these meet above the nasal canal in front of the nasal bones for an extent of about three lines, and thus exclusively form the boundary of the single, oval, and terminal external nostril. The lower or palatal process of the intermaxillary extends backwards in the form of a long and slender pointed process which is wedged into a fissure of the superior maxillary bone.

The anterior palatal or incisive foramen is a single large elongated fissure extending from the narrow anterior symphysis of the intermaxillaries backwards, for some distance, between the palatal processes of the maxillaries. At the back part of the bony palate a narrow fissure extends forwards between the pterygoid bones, and the intermediate extent of the bony palate is entire, or presents only a few minute perforations. The palatal bones, if originally distinct, soon become confluent with the maxillaries. There was no separate osseous style representing the malar bone between the zygomatic processes of the maxillary and temporal bones in the skull here described.*

The zygomatic process of the *superior max-*

* The very able anatomists, MM. Laurillard and Duvernoy.

* Cuvier says, "Entre ces deux apophyses est un très-petit filet qui represent le jugal." Cuvier, Ossem. Foss. 4to., vol. v., p. 145.

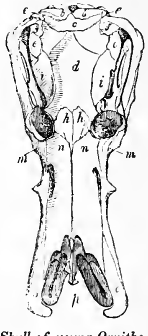
illary bone (fig. 169, *m)* extends backwards as far as the posterior boundary of the zygomatic or temporal fossa; the palatal process extends along the floor of the orbit in a similar form and to nearly the same extent. The orbit is marked off from the temporal fossa by merely a slight ridge extending down and across the suture joining the frontal and sphenoid bones.

The skull of the Echidna differs from that of the edentulous Manis and Myrmecophaga in the completion of the zygomatic arches, in the unclosed state of the tympanic cavity, in the large size of the foramen incisivum, and the surrounding of the external nostrils by the intermaxillary bones alone: it differs also in the smaller relative distance between the posterior palatal fissure and the superior maxillary bones, and in the apparent absence of the palatine bones, the presence and interposition of which between the pterygoid and maxillary palatal plates elongates the palate in the placental Anteaters at the part where it is relatively shorter in the Echidna. In the modification of the pterygoid plates of the sphenoid to complete the posterior nasal canal, the Echidna manifests an interesting resemblance with the great Anteater; but it differs from this, as from every other mammiferous species, in the palatal plates contributed by the petrous bones to the broad posterior part of the roof of the mouth which supports the horny palatal teeth. Cuvier describes the posterior palatal fissure as extending between the palatine bones, and therefore regards the plates, which are here affirmed to be developed from the petrous bone, as being the pterygoid processes of the sphenoid; and, according to this view, he truly observes that their horizontal position is very remarkable;* but he might have added, that their share in the formation of the tympanic cavity was not less so. The same determination of the bones composing the posterior part of the osseous palate of the Echidna is repeated in the Leçons d'Anatomie Comparée, 1837, p. 454. If, however, the sphenoid be separated from the occipital bone, which was easily done in the young skull of the Echidna represented in *figs.* 169 and 170, the horizontal plates, described by Cuvier as pterygoids, are left behind, not as separate bones, but as continuous portions of the petrous elements of the temporal, which form, at the same time, part of the base of the cranial cavity, complete the inner wall of the tympanum, and the anterior part of the Eustachian groove. The palatines of Cuvier are developed from the sides of the basi-sphenoid, and almost immediately bend inwards and meet below the nasal canal, which they thus prolong posteriorly, as in the *Myrmecophaga;* and they are separated posteriorly, also, as in that genus, by an acute fissure, presenting unequivocally the same modifications which characterize the pterygoids in the placental Anteaters, and in the Crocodile. The suture dividing the pterygoids from the palatines in the Echidna is obliterated, if it ever existed; or the true palatines may be confluent with the palatine processes of the maxillary bones.

* Cuvier says, "Une echancrure digne et profonde sépare les palatins en arrière. Le plan de chacun d'eux est continué en dessous par une apophyse ptérygoide, qui ici, chose bien remarquable, est horizontale ou à peu pres: elle contribue à former la cavité de la caisse."—Ossem. Fossiles, l. c. p. 146. Meckel is silent on this subject.

Some of the Marsupials, as the Wombat, resemble the Echidna in the open state of the tympanic cavity in the dry skull; but the most essential points of correspondence with the cranial anatomy of the Echidna are found, as might be expected, in the Ornithorhynchus. In this Monotreme the tympanic cavity *(fig.* 173, A, *k)* is a simple excavation at the under part of the petrous bone; the periphery of the opening, which looks almost directly downwards, is encompassed by the tympanic and malleal bones, *(fig.* 173, D, *a*, *b*,*)* the outer and anterior part of the circle being formed by the os tympanicum. The tympanic cavity is relatively smaller, but is defended posteriorly by a larger process sent downwards by the petrous bone near its outer side. The petrous bone here forms no palatal process, but the bony roof of the mouth is terminated by the pterygoid plates, *(fig.* 173, A, *i*,*)* which meet below the nasal canal, as in the Echidna, but are not divided by any posterior fissure. In a skull of the Ornithorhynchus, in which the suture dividing the palatine processes of the maxillary bones from the bony palate posterior to them remains, there is no trace of a division between the pterygoid and palatine bones, which contribute to complete the osseous palate *(fig.* 173, A, *e*).

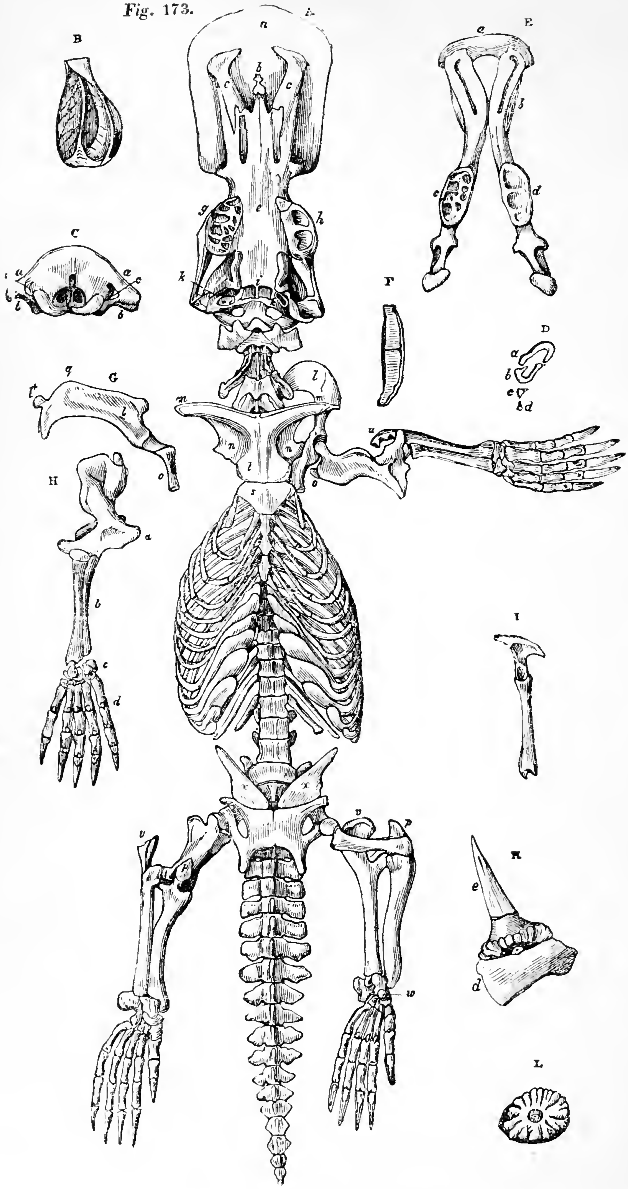
Fig. 172.



Skull of young Ornithorhynchus. (Original.)

The occipital bone of the young Ornithorhynchus corresponds with that of the Echidna in the relative size and position of its four component parts. The ex-occipitals are shown at *fig.* 172, *b*, *b*, and the supra-occipital at *c*. The *petrous* element of the temporal (*e*) likewise sends a thin plate to form the posterior part of the side of the cranium, but it does not intervene between the parietal bone and squamous part of the temporal, as in the Echidna. The middle of the upper margin of the cranial plate of the petrous bone is notched, and a small vacuity here intervenes between the petrous and parietal bones, which is closed by the squamo-temporal *(f)*, the upper margin of which overlaps the descending posterior angle of the parietal bone (*d*). The form of the *squamous* element of the temporal is very remarkable in the Ornithorhynchus: its ascending cranial or proper squamous portion is a small sub-quadrilateral bony scale, narrower antero-posteriorly, but higher than the corresponding part in the Echidna; articulated by its squamous margin with the parietal and

Fig. 173.



Skeleton of the Ornithorhynchus. (Meckel.)

petrous, but separated from the latter, at its lower half, by a fissure analogous to but wider than the canal which traverses the squamous union of the same bones in the Echidna. The base of the squamous plate is contracted but thickened to form the origin of the zygomatic process: it sends inwards a thin plate, concave externally, which forms the glenoid cavity for the lower jaw, and is applied against the basal part of the petrous bone. The glenoid plate is equal in size to the squamous process. They meet at a right angle, and, from the tubercle developed from their union, external to the glenoid cavity, the zygomatic process is continued forwards to join that which is sent off by the superior maxillary bone. I could not find any distinct malar bone in the young *Ornithorhynchus*. The same arguments against considering the squamous bone to be the malar apply to this Monotreme as have been used in reference to the Echidna.

The *parietal* bone (*fig.* 172, *d*) forms the chief part of the upper region of the skull; it is longer in proportion to its breadth than in the Echidna. Both the lambdoidal and coronal sutures are squamous, and the parietal overlaps the frontal bones. There is no trace of sagittal suture; the bony falx is developed from the line which that suture would occupy. The lateral connexions of the parietal differ from those in the Echidna by its union with the squamous portion of the temporal bone, as above-mentioned.

The *frontal* bones (*h*, *h*) are relatively smaller than even in the Echidna: they were divided by a suture in the specimen described. The form of their exposed surface is shown in *fig.* 172, *h*, *h*.

The side of the skull anterior to the petrous bone is formed by the great ala of the *sphenoid* (*fig.* 172, *i*), which is joined by a well-defined linear harmonia to the parietal bone.

The Ornithorhynchus differs from the Echidna in the large vacuities in the floor of the skull behind and in front of the tympanic cavity, the one representing the combined jugular and condyloid foramen, the other the oval foramen, between which the body of the sphenoid also presents two membranous spaces. The skull differs also in the larger size of the foramen rotundum, in the stronger zygomata, the more complete orbit, and the singular modification of the bones supporting the beak. The cranial cavity is proportionally smaller and shallower in the Ornithorhynchus. The sutures of the cranial bones are much sooner obliterated, and the whole upper and lateral parietes then consist of a thin continuous dense plate of bone without diploë.

The resemblance which the Ornithorhynchus offers in this respect to the class of Birds is noticed by Meckel.

The oblique canal, (*fig.* 173, c, *c*,) which traverses the squamous suture between the petrous and squamous portions of the temporal in the Echidna, is so much shorter and wider in the Ornithorhynchus that it appears to detach from the side of the cranium a distinct superior column or root (*fig.* 173, c, *a*) to the posterior commencement of the zygomatic arch. An analogous canal runs between the tympanic and mastoid bones in the skull of the Crocodile, and is dilated to great width in the Lizards; but the presence of a distinct tympanic bone in the usual position in the Ornithorhynchus nullifies the supposition that the upper root of the zygoma can be the analogue of the os quadratum in the Ovipara.

The articular surface for the lower jaw (*fig.*173, c, *b*) is much more distinctly developed than in the Echidna; it occupies the base of the zygoma, is extended and concave transversely, narrower and slightly convex from before backwards: it is not defended by any posterior process. The zygoma is complete, and consists of a nearly vertical straight plate of bone, expanded at its anterior or maxillary extremity, where it sends upwards an angular process bounding the orbit posteriorly, and bends downwards to support the broad alveolus of the horny molar tooth (*fig.*173, A, *g*, *h*). The orbits are small and directed obliquely upwards and outwards. The skull is more contracted between them than in the Echidna, but anterior to them it begins to expand, becomes flattened horizontally, then bifurcates, and the two depressed branches, after slightly diverging, terminate each by an inwardly inflected process, the extremities of which are half an inch apart. The space intercepted by the facial fork is the external bony nostril (*fig.* 172, *p*), which is thus left incomplete anteriorly. The forms and proportions in which the bones of the face enter into the formation of the external nasal aperture are illustrated in the figure of the cranium of the Ornithorhynchus given by Pander and D'Alton,* and I have verified the accuracy with which the sutures are there delineated. Cuvier† supposed the facial forks to be formed by the intermaxillary bones, and describes a small bone in the middle of their interspace (*fig.* 172, *p*) suspended in the cartilage of the upper mandible, and with an emargination on each side of its inferior plate, which he conjectured might represent the nasal bones and the palatine part of the intermaxillary bones. The true nasal bones (*fig.* 172, *n*, *n*) are, however, as shown by Pander and D'Alton, analogous in situation to and more largely developed than those of the Echidna. They commence each by an angular process, which overlaps the frontal, and extends into the inter-orbital space. They are continued forward of equal breadth, and have their anterior extremity obliquely truncated and terminated in a fine point, which extends to the middle of the inner side of the facial fork. The nasal bones thus form the posterior half of the boundary of the bony nostril. The superior maxillary bone (*fig.* 172, *m*, *m*), after sending off a process (*c*), which curves over the ant-orbital foramen, extends forwards

* Skelete der zahnlosen Thiere, 1825, (tab. ii. fig. *a*.)

† Leçons d'Anat. Comp. 1837, ii. p. 455.

in a pointed form along the outer side of the facial fork as far as the nasal does on the inner side, and an angular fissure is intercepted between the anterior extremities of these bones into which the pointed posterior part of the intermaxillary bone (*fig.* 172, *o, o*) is inserted. The anterior half of the facial fork with its inflected end is wholly formed by the intermaxillary bones, which thus bound the anterior half of the wide external nasal aperture. The small detached intermediate bone (*fig.* 173, A, *b*) may be regarded as a separate centre of ossification of the palatine process of the intermaxillaries, and of the middle stem which divides the anterior nostrils in birds and lizards.

The *vomer* forms a bony septum, dividing the whole extent of the nasal canal from the spine of the sphenoid forwards.

There is a small lachrymal foramen (*fig.* 169, *l*) at the anterior and inner part of the orbit in both the genera of Monotremes; a little lower down is the commencement of the ant-orbital canal. This canal branches in the Echidna, and terminates on the outer side of the maxillary bone by a succession of small foramina; but in the Ornithorhynchus, where it transmits a much larger sensitive nerve, it divides into three canals, of which one emerges beneath the uncinated process of the maxillary above mentioned; a second descends and opens upon the palate; and the third passes forwards into the substance of the facial fork, and terminates by a large foramen at the outside of the intermaxillary bone.

On the exterior of the cranium the ridges indicating the extent of the temporal muscles are clearly developed in the *Ornithorhynchus*, and correspond with the stronger zygomata and the more complete apparatus for mastication in this Monotreme. Four linear impressions upon the upper surface of the skull diverge from the middle of the lambdoidal ridge, and terminate at the temporal ridges. The occipital foramen (*fig.* 173, C) has a vertical plane, as in the Echidna, and has a similar rounded notch at its upper part.

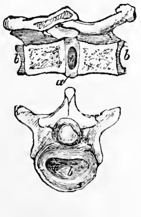
The interior of the skull offers many unusual modifications. The sella turcica is elongated and narrow in both Monotremes; it is bounded by two very distinct lateral walls in the *Echidna*. The posterior clinoid processes are chiefly remarkable for their height in the Ornithorhynchus. The semicircular canals stand out in high relief in this species, as in Birds. In the Echidna the ethmoid encroaches upon the anterior part of the cranial cavity in the form of a large convex protuberance made by the posterior wall of the olfactory cavity, and a very extensive cribriform plate is developed. In the Ornithorhynchus the olfactory tract is comparatively small, in the form of a depression, and the nerve escapes by a single foramen at the anterior part of the ethmoidal plate. This is likewise an interesting mark of affinity to the bird and reptile; but the most remarkable and characteristic feature in the interior of the skull of the Ornithorhynchus is the bony falx (*fig.* 173, B). This is not present in the Echidna. The tentorium is membranous in both Monotremes.

The lower jaw consists in the Echidna of two long and slender styliform rami without a symphysial joint, but loosely connected together at their anterior extremities. An angular process divides the horizontal from the ascending ramus, which rises at an open angle and terminates in a small oblong convex condyle. A short obtuse coronoid process extends from the upper part of the horizontal ramus as far in advance of the angle as the condyle is behind it. The rest of the ramus is rounded like a rib, and diminishes to the anterior extremity. The dental canal commences below the coronoid process and divides in its progress, one branch terminating near the middle of the smooth alveolar border, the other close to the end of the ramus. In no Mammiferous animal does the lower jaw bear so small a proportion to the skull or to the rest of the skeleton as in the Echidna.

In the Ornithorhynchus the lower jaw is much more developed (*fig.* 173, E). Each ramus commences posteriorly by a large subhemispherical condyle, the convexity of which, so characteristic of the Mammalian class, is strongly marked. The ascending ramus is nearly horizontal, flattened below, and continued upwards in the form of a low vertical compressed plate, on each side of which there is a deep fossa. The ascending is continued by a gentle curve into the horizontal ramus, and the angle of the jaw is very feebly indicated. The horizontal ramus suddenly expands and sends off above in the same transverse line two short obtuse processes, both of which might be termed 'coronoid;' this structure is peculiar to the Ornithorhynchus. The innermost process (*c*), although the largest, is the superadded structure, as it affords insertion to the internal pterygoid. About two lines anterior to these processes the upper border of the horizontal ramus expands to form the shallow oblong alveolus (*e*) for the horny grinder. Its floor is perforated by several large foramina. The dental canal divides; one branch opens by a wide elliptical foramen on the outside of the ramus immediately anterior to the alveolus, the other terminates at the lower part of the end of the ramus. The rami of the jaw converge and are united at a symphysis of more than half an inch in length; there they become expanded and flattened, then again disunite, and are continued forwards as two spatulate processes (*b*), which diverge from each other to their broad rounded terminations, and are situated just behind the inflected extremities of the similarly separated inter-maxillaries (*fig.* 173, A, *c, c*). On the outer sides of the upper surface of the broad symphysis are the long and narrow sockets of the two anterior trenchant horny teeth. The Monotremes differ from the Marsupials in the absence of the inflected process developed from the angle of the lower jaw.

Of the vertebral column.—Both Monotremes have twenty-six true vertebræ, of which the seven first are cervical. In the Echidna sixteen, and in the Ornithorhynchus seventeen, of the following vertebræ support long and functional ribs, so that there are three lumbar vertebræ in the Echidna, and but two in the Ornithorhynchus, which thus resembles the Lizards in the great proportion of the trunk which is encompassed by the costal arches. Another approximation to the Oviparous type is made by the long-continued separate state of the short cervical ribs in both Monotremes: these in a young but nearly full-grown Echidna are detached from all the cervical vertebræ except the atlas. The vertebral end of the cervical rib is bifurcated; the lower branch, representing the head, is articulated to the transverse process or tubercle developed from the body of the vertebra; the upper branch, representing the costal tubercle, is articulated to a transverse process developed from the side of the base of the neural arch. In the Ornithorhynchus the cervical ribs appear to become earlier anchylosed to the vertebræ, except as regards the axis, in which the broad costal appendage retains its original independence throughout life, and is slightly moveable upon the confluent extremities of the two transverse processes. In the succeeding vertebræ the space intercepted between the two transverse processes, the vertebra, and the costal rib, forms the so-called ‘perforation of the transverse process’ for the vertebral artery in human anatomy. In the Echidna, above alluded to, the ‘neurapophyses’ or vertebral plates of the atlas, which together form the neural or spinal arch, were unanchylosed at their upper or spinal extremities. The atlas of the Ornithorhynchus is chiefly distinguished from that of the Echidna by the continuation, from the lower part of its slender body, of two long diverging processes which are developed in the strong tendons of the *recti capitis antici* muscles. The spine of the dentata is broad and high in both Monotremes; those of the other cervicals progressively diminish in size in the Ornithorhynchus, but become at once nearly obsolete in the Echidna. The transverse and spinous processes are of moderate size in the rest of the true vertebræ, but are largest in the lumbar region. The posterior oblique processes are single in these vertebræ. The articular surfaces of the vertebræ, which are slightly concave, are joined together by a thick circular band of ligamentous fibres (*fig.* 174, *a*) attached to the circumference of the articular surface, enclosing a central oblate spheroidal cavity (*b*) lined by a synovial membrane and filled with fluid.

Fig. 174.



Intervertebral cavities, Echidna. (Original.)

The *ribs* are long and slender in the Ornithorhynchus, somewhat stronger in the Echidna. The first is flattened, the rest are cylindrical. Each rib is articulated by a single joint, uniting the head to the vertebral interspace, or to the side of the centrum, as in the two last pairs: the tubercle, though small, is distinctly developed, and defines the neck of the rib, although it does not join the transverse process of the vertebra.

Meckel's statement, ‘tuberculum adest nullum,’ is applicable only to the last three or four pairs of ribs. The first six pairs are joined to the sternum in both the Ornithorhynchus and the Echidna. Six pairs of ossified sternal ribs (hæmapophyses*) are articulated to the sternum in the Echidna; the first four are nearly straight and sub-cylindrical; the fifth and sixth are expanded. Five pairs of ossified sternal ribs are present in the Ornithorhynchus, to which the second to the sixth vertebral ribs inclusive are joined by shorter intervening cartilaginous pieces of a similar form. The first rib in the Ornithorhynchus is joined to the sternum by cartilage alone. The interposed cartilages, which thus form a third element in the costal arch, repeat a structure common in crocodiles, and may be regarded as the homologues of the costal appendages in the ribs of birds, which in this class are removed from the interspace of the vertebral and sternal rib, and articulated to the vertebral piece.

The cartilages of the false ribs in both genera are singularly expanded and flattened, and present an imbricated arrangement, gliding upon each other with a slight yielding motion: the last vertebral rib, which is the shortest and straightest, is terminated by a short free cartilage. Many bone-corpuscles are scattered through these cartilages.

The ordinary *sternum*, to which the true ribs articulate, consists of four ossicles, and in the Echidna a fifth is developed in the base of the ensiform cartilage; the most anterior of these ossicles (*fig.* 173, A, *s*) has the usual expanded hexagonal form and large proportions of the manubrium sterni, and receives, besides the first and part of the second pair of ribs, the extremities also of the coracoid bones. The ensiform cartilage in the Echidna presents an elongated oval form with a central perforation. A large T-shaped episternal bone (*fig.* 173, A, *t*) is articulated to the anterior surface of the manubrium sterni; it is the key-bone of the complicated scapular arch.

The *sacrum* consists in the Ornithorhynchus, as in most Saurians, of two vertebræ, distinguished by the greater breadth and thickness of their transverse costal processes. In the Echidna there are three sacral vertebræ.

There are thirteen caudal vertebræ in the Echidna (*fig.* 168). The first is the largest, with broad transverse processes, the rest progressively diminishing, and reduced, in the six last, to the central element. The Ornithorhynchus (*fig.* 173, A) has twenty-one caudal vertebræ, of which all but the last two have

* In the complete vertebræ which encompass the centre of the vascular system, the hæmapophyses or halves of the chevron-bone, or inferior vertebral laminæ, are retained, together with the inferior or hæmal spine. The series, sometimes anchylosed, as in Man, of these spines forms the ‘sternum:’ the inferior laminæ or hæmapophyses are the sternal ribs.

transverse processes, and the first eleven have also spinous and articular processes. The transverse processes are broad and depressed; they gradually increase in length to the tenth caudal, then as gradually diminish to the twentieth; their extremities are expanded, and, from the fifth backwards, are thickened and tuberculate. The spinous processes progressively diminish in height from the first caudal. The first six caudal vertebræ have both posterior and anterior oblique processes, and are joined together both by these and by the articular surfaces of the body: the anterior articular processes are present, but progressively diminish in size from the seventh to the sixteenth vertebræ, and are not subservient to their reciprocal articulation. Inferior spinous processes are developed from the bodies of the third to the nineteenth caudal vertebra inclusive; but there are no hæmapophyses articulated to the vertebral interspaces, as in many Marsupials and the Edentata. In the Echidna the inferior spinous processes are absent; but rudiments of hæmapophyses are connected with the interspaces of one or two of the middle vertebræ of the tail. The caudal vertebræ in the Ornithorhynchus are of nearly the same length to the two last; they progressively diminish in vertical diameter as they recede from the trunk, and are chiefly remarkable for their breadth and flatness; resembling in this respect, as Cuvier has observed, the caudal vertebræ of the Beaver, and we might add those of the Cetacea; the horizontally extended tail having a similar relation to the frequent need which an aquatic animal with hot blood and a quick respiration of air has to ascend rapidly to the surface of the water.

Of the pectoral extremities.—Cuvier* justly observes that the most remarkable part of the osteology of the Monotremes is the organization of the shoulder; which corresponds with that of birds, and still more with that of lizards.

Had these anomalous Mammals been extinct, and their fossilized skeleton alone, as in the Ichthyosauri, been preserved for the contemplation of the naturalist, the perplexity which the combination of this structure with the mammalian conditions of the skull and vertebræ would have occasioned may be readily conceived.

The scapula (*l*) is represented detached, with the coracoid (*o*), at G, *fig.* 173; *l** is the cartilage appended to the short convex base. The scapula is long, narrower than in most Mammalia, and has its posterior vertebral angle so much produced, as to give it a resemblance to the scapula of the bird and saurian: this resemblance is farther increased by the origin of the spine close to the anterior costa, and by the spine being bent forwards so as to seem to form a continuation of the external surface of the scapula, which is thus rendered concave in the Ornithorhynchus. The spine, however, terminates in a freely projecting acromion.

The true anterior costa is, in this Monotreme, represented by a ridge which traverses obliquely the inner and convex side of the scapula, from the anterior vertebral angle to the neck of the bone. In the Echidna this ridge is nearly obsolete, and the spine of the scapula is bent so as to form a more direct continuation of body of the scapula with the plane of which it is nearly parallel: the acromial termination is slightly twisted.

Both Cuvier and Meckel describe the spinous process of the scapula as the anterior margin, (superior costa in human anatomy,) and consequently consider the spine of the scapula as being absent. Cuvier says, "Le bord antérieure descend presque droit jusqu'à l'endroit ou il se courbe en dedans pour former une apophyse, qui porte la fourchette." Meckel recognises this process as the acromion: "Margo anterior partis superioris versus inferiora extrorsum primo flexus, dein eminentiam, acromion, antrorsum et introrsum versam, emittit." The 'margo anterior' of Meckel, 'bord antérieure' of Cuvier, is, in fact, the true spine of the scapula, and the true 'margo anterior' is the ridge above described. The proof of this is afforded by the origin of the supra-spinatus muscle which occupies the space between Meckel's 'margo anterior' and the ridge which I regard as the true anterior costa, and which is not noticed by either of the anatomists above quoted.

Since the scapula is peculiarly characterized in Mammalia by the presence of a spine and in Ovipara by its absence, its recognition in the Monotremes, under the modification by which its apparent absence is occasioned, and the transition to the oviparous type of this bone is effected, becomes a subject of especial interest.

The whole scapula is broader, thicker, and less curved in the Echidna than in the Ornithorhynchus. In both Monotremes, the posterior margin or costa is concave, most so in the *Ornithorhynchus*, and in both it is turned towards the trunk, so that the sub-scapular surface looks obliquely forwards and inwards. The *articular* surface is divided into two facets: the one, internal and flat, articulates with the coracoid; the other, external, is slightly concave, and contributes, with a similar but narrower concave surface of the coracoid, to form the glenoid cavity for the humerus.

The *coracoid* (*fig.* 173, G, *o*) early coalesces with the scapula in the Ornithorhynchus; it maintains its independent condition to a later period in the Echidna. In both it is a strong, subcompressed, subelongate bone, expanded at both ends; one of these is articulated and anchylosed with the scapula, as above described; the other is joined to the anterior and external facet of the manubrium sterni. The posterior margin of the coracoid is concave and free; the anterior margin is straight and articulated with a thin broad irregularly quadrilateral plate of bone in the Ornithorhynchus, and a thicker and nar-

* Ossem. Foss. v. pt. 1, p. 146.

rower corresponding bone in the Echidna. These bones, which are called the 'epicoracoids' (*fig.* 173, A, *n n*) are joined by their median margin to the stem of the episternal, and by their anterior margins to its transverse branches, which are overlapped by the epicoracoids.

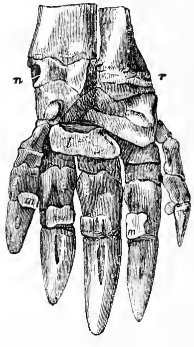
The true or acromial *clavicle* (*fig.* 173, A, *m m*) is a long, slender, compressed, slightly bent bone, continued from the articular cavity at the end of the acromion to near the median line of the episternum, anterior to but parallel and in contact with the branches of the episternum, with which the clavicles finally coalesce, but at an earlier period in the Ornithorhynchus than in the Echidna. These clavicles are the homologues of the os furcatorium in the bird: the T-shaped episternum (*fig.* 173, A, *t*) is feebly represented in birds by the median process continued forwards between the coracoid articular cavities from the fore part of the sternum. It is in Lizards, and especially in the extinct Ichthyosaur, that the episternum presents the same form, development, and relation to the clavicles, as in the Monotremes. The epicoracoids again are wanting in the bird, but they are present in lizards, and the remarkable breadth of the coracoid in the Enaliosauria is due to their presence, although, singularly enough, they are anchylosed to the coracoids in these extinct reptiles, while in the warm-blooded Monotremes they remain separate. In the Echidna they are articulated with the coracoid by a true synovial joint. To render the resemblance between the Monotreme and the Bird complete, in respect of the structure of the scapular arch, the episternum must be reduced to a short and simple process attached to the anterior part of the manubrium sterni, the epicoracoids must be removed, and the clavicles anchylosed together at their mesial extremities.*

The *humerus* is a short and strong bone, expanded at both extremities, and, as it were, twisted half round upon itself. The proximal expansion terminates by a broad thick convex border, the middle part of which is developed into the articular head, which is so adapted to the glenoid cavity, that the bone is maintained in a horizontal position, and the distal expansion is nearly vertical. The deltoid and pectoral crests are strongly developed; both condyles are remarkably produced, especially the internal one, which is perforated. (*Fig.* 173, H, *a.*) The distal articular surface scarcely occupies a fourth part of that broad termination of the humerus: it presents, in the Echidna (*fig.* 168), a convex tubercle, which is broadest in front, for the articulation of the radius, narrow behind, for that of the ulna. The articular surfaces of both anti-brachial bones are concave: so that the elbow-joint admits freely of flexion and extension, abduction and adduction, but is restricted in the movement of rotation.

* For a full and elaborate discussion of the various opinions which have been offered respecting the homology or signification of the complicated apparatus of the shoulder in the Ornithorhynchus, the reader is referred to Meckel, 'De Ornithorhyncho,' &c. pp. 12-15.

The *radius* and *ulna* are in contact and pretty firmly connected together through nearly their whole extent; the interosseous space being reduced to a slight fissure. The *ulna* is chiefly remarkable for the olecranon, (*fig.* 173, A, *u*,) which is bent forwards upon the humerus, and transversely expanded at its extremity, especially in the Ornithorhynchus, in which the lower or inner angle of the expanded extremity is considerably produced. The shaft of the ulna is compressed, and increases in breadth, in the Echidna, as it approaches the broad carpus. In the Ornithorhynchus it is bent like the italic *f*, is more cylindrical, and more suddenly expanded at the distal end. The *radius* offers little worthy of notice, except that in the Ornithorhynchus it is flattened next the ulna, and so applied to that bone as to prevent altogether a rotation of the hand upon the ulna. In the Echidna the distal articular surface of the ulna (*fig.* 175, *n*) presents two convex trochleæ separated by a median concavity; that of the radius (*fig.* 175, *r*) offers a reverse condition: here two concavities are divided by a median convex ridge; all the four facets at the carpal joint of the antibrachium are in the same transverse line. The two radial concavities receive the two articular convexities of the broad scapho-lunar bone (*fig.* 176, *a*): the two convex trochleæ of the ulna play upon two concavities, one-half of each of which is contributed by the cuneiform (*fig.* 176, *b*) and pisiform bones (*c*). This complicated joint limits the movement of the hand upon the fore-arm to flexion and extension.

Fig. 175.



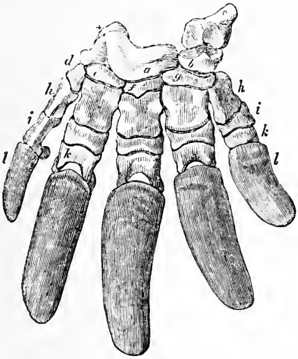
Bones of fore-foot, palmar aspect, Echidna setosa. (*Original.*)

Notwithstanding the confluence of the scaphoid with the lunar bone in the *carpus* of the Echidna, as in that of the Marsupials and Carnivora, it includes eight ossicles, a small sesamoid bone (*fig.* 176, *) being developed in the tendon of the flexor carpi radialis, and articulated with the scapho-lunar bone and radius. The distal series of the carpus includes the four normal bones, the trapezium (*fig.* 176, *h*) supporting the innermost digit or pollex, the trapezoides (*g*), the index, the os magnum (*f*), which is almost the smallest, sustaining the medius, and the unciforme (*e*) the two outer digits: this description is taken from the Echidna: the only essential difference observable in the Ornithorhynchus is the contribution by the os magnum of a greater share to the articulation with the ring-finger.

In the Echidna all the bones of the fore-extremity are relatively larger and stronger than in the Ornithorhynchus, but this difference is especially remarkable in the metacarpal bones and two first rows of phalanges *fig.* 176, *h*, *i*, *k*), which are singularly short, broad, and thick. The palm is strengthened by two large sesamoids developed in the flexor tendons in the Echidna; these are sometimes confluent (*fig.* 175, *l*). The number of phalanges in both Monotremes is the same as in other Mammals, viz. two to the thumb and three to each of the fingers. This is not the case in any Saurian, and the retention of the Mammalian type at the peripheral segment of the limb, with the singular deviation from it at the central supporting arch, is not one of the least remarkable points in the osteology of the Monotremes.

There is a sesamoid bone at the palmar aspect of each of the distal articulations of the phalanges in the Echidna (*fig.* 175), and at all the digital articulations in the Ornithorhynchus (*fig.* 173, H, *d*).

Fig. 176.

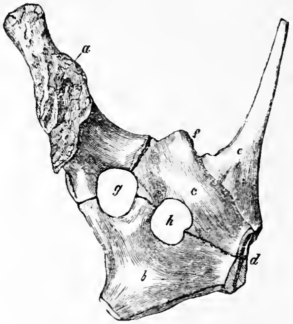


Bones of the fore-foot, Echidna hystrix.
(Cuvier.)

The ungual phalanges are long, depressed, nearly straight, of great strength in the Echidna, in which each of them is perforated at the palmar aspect (*fig.* 175).

Of the pelvic extremities.—The pelvis of the Monotremes bears a resemblance to that of Reptiles in the length of time during which the three components of each os innominatum remain distinct, especially in the Echidna; and in the great development of the ilio-pectineal spine, which equals in size that of the tortoise, in the Ornithorhynchus; the pelvis of the Echidna resembles that of Birds in the perforation of the acetabulum (*fig.* 177, *g*), but the pelvis in both Monotremes chiefly resembles that of the higher implacental Mammalia in the presence of the marsupial bones.

Fig. 177.



Internal view of pelvis, Echidna setosa.
(Original.)

The *ilium* (*fig.* 177, *a*) is a short, strong, trihedral bone, with the upper extremity expanded and everted in the Ornithorhynchus. The *ischium* (*b*) has its tuberosity prolonged backwards in an obtusely-pointed form in the *Ornithorhynchus*. The *pubis* in the same animal, besides having the spinous process directed forwards, gives off a second smaller process, which projects outwards; this process is present, but less developed in the Echidna (*fig.* 177, *f*). The pubis (*c*) and ischium contribute an equal share to the formation of the foramen obturatorium (*h*) and to the symphysis which closes the pelvis below: the symphysis is relatively shorter in the Echidna (*d*) than in the Ornithorhynchus.

The *marsupial bones* (*fig.* 173, A, *x x*, 177, *e*) are relatively larger and stronger in the Monotremes than in the ordinary Marsupialia, the Koala excepted; their base extends along the anterior margin of the pubis from the symphysis outwards to that of the spinous process (*fig.* 177, *f*); they are relatively longer in the Echidna (*e*) than in the Ornithorhynchus; they always remain moveably articulated with the brim of the pelvis.

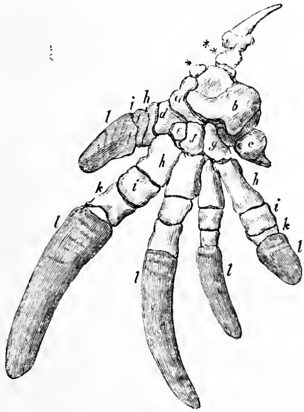
The *femur* is short, broad, and flattened; its head rises, like that of the humerus, from the middle of a broad expanded proximal end, having on each side a strong process, the outer one representing the great, the inner one the small trochanter. In the Echidna a projecting ridge extends from the great or outer trochanter beyond the middle of the bone; the whole of the inner part of the shaft is bounded by a trenchant edge; both outer and inner margins of the bone are trenchant in the Ornithorhynchus. The distal end of the femur is expanded transversely, but compressed from before backwards. The rotular trochlea is flat transversely, convex vertically, in the Echidna; it is hardly definable when the cartilage is separated from the bone; but the *patella* itself is well developed, and ossified in both Monotremes (*fig.* 173, A, *p*).

The *tibia* is straight in the Echidna, but bent, with the convexity next the fibula, in the Ornithorhynchus; its cristæ are slightly marked.

The *fibula* is slightly bent in the Echidna, but is straight in the Ornithorhynchus; in both Monotremes it is longer than the tibia by the extent of a process which rises upwards beyond the proximal articulation of the fibula, and most strongly expresses the analogy of this bone with the ulna: this process (*fig.* 173, A, *v*) reaches half way up the back of the femur in the Ornithorhynchus, and, like the olecranon, is greatly expanded at its termination. Cuvier* indicates the resemblance of this structure in the Monotremes with the fibula and the supernumerary bone imposed upon its enlarged proximal end in the pedimanous Marsupials.

The *tarsus* (*figs.* 178, 179) consists of a scaphoid (*a*), astragalus (*b*), a calcaneum (*c*), three cuneiform bones (*d,e,f*), and a cuboid (*g*) in the Echidna; but the cuboid in the Ornitho-

Fig. 178.

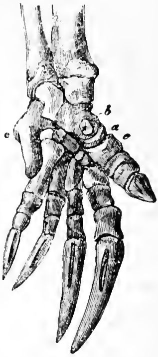


Bones of hind-foot, Echidna hystrix. (Cuvier.)

rhynchus is divided into two bones, as in some Reptiles, one for the fourth and the other for the fifth metatarsal bones. In both Monotremes there is a sesamoid bone (*fig.* 178, *) placed at the interspace between the astragalus and the naviculare; a second supernumerary bone (**) is articulated to the posterior part of the astragalus, and supports the perforated spur which characterizes the male sex (*fig.* 173, K, *d*).

The calcaneum of the Ornithorhynchus terminates by sending outwards a short obtuse tuberosity; in the Echidna this part is more slender, and is singularly directed inwards and forwards, nearly in a line with the digits (*fig.* 179, *e*).

Fig. 179.



***Bones of hind-foot, plantar aspect, Echidna setosa.* (*Original.*)**

The astragalus in the Ornithorhynchus presents a double trochlea above for the tibia and fibula, and a depression on its inner side, which receives the incurved malleolus of the tibia, almost as in the Sloths. The toes have the same number of bones as in other Mammalia; their size and form are more alike in the two Monotrematous genera than those of the fingers: the ungual phalanges, like the claws they support, are more curved than those on the fore foot, but like them they are perforated on their inner and concave side (*fig.* 179).

OF THE MUSCULAR SYSTEM.

The figure (180) here given from Meckel* illustrates some of the most instructive peculiarities of the muscular system of the Ornithorhynchus. The animal is dissected from the ventral surface; the great cutaneous muscle, the 'panniculus carnosus' (1), is reflected from the right side, and the deeper-seated muscles are shown on the left. The panniculus carnosus, which is remarkable for its thickness, encompasses nearly the whole body, adhering most firmly to the external skin, but separated from the subjacent muscles, especially where it covers the thorax, abdomen, the arm, and the thigh, by a copious and lax cellular tissue; and in the female, at the abdominal region, by the mammary glands. The fibres are chiefly longitudinal, but at the lower part of the neck become transverse. The obtuse posterior end of the muscle is attached by three or four fasciculi to the dorsal aspect of the transverse processes of the caudal vertebræ. The legs and the arms protrude through oblique apertures in this muscular tunic; some of the anterior fasciculi are inserted by a short tendon into the pectoral ridge of the humerus; and others, still more anterior, are attached to the cranium, the lower jaw, and lower lip. A strip of fibres, which is cut off at 1*, is attached to the os hyoides; another fasciculus (1′) spreads over the cheek-pouch, and assists in emptying that receptacle of the food.

The *trapezius* (9) is divided into two muscles; the posterior portion is an oblong slender triangle arising by a broad tendon from the tenth and eleventh vertebræ and ribs, and inserted by a short strong tendon in the anterior extremity of the spine of the scapula; the anterior portion is shorter, but broader, and is subquadrangular; it arises from the occiput and tendinous raphé

* Ossem. Foss. v. pt. i. p. 153.

* De Ornithorhyncho, &c. tab. v.

connecting it with its fellow of the opposite side (called 'ligamentum nuchæ' by Meckel), and is inserted into the spine ('margo anterior scapulæ,' Meckel) and acromion process of the scapula, and into the outer half of the clavicle.

The *latissimus dorsi*, a very long and broad muscle, arises from the spines of all the dorsal and lumbar vertebræ, and from the eleven posterior ribs; it is inserted by a broad and strong tendon into the distal half of the ulnar margin of the humerus. At its anterior part this muscle may be separated into a superficial and deep stratum.

The *rhomboideus* is a single muscle, but thick and long, extending from the occiput to the narrow base of the scapula.

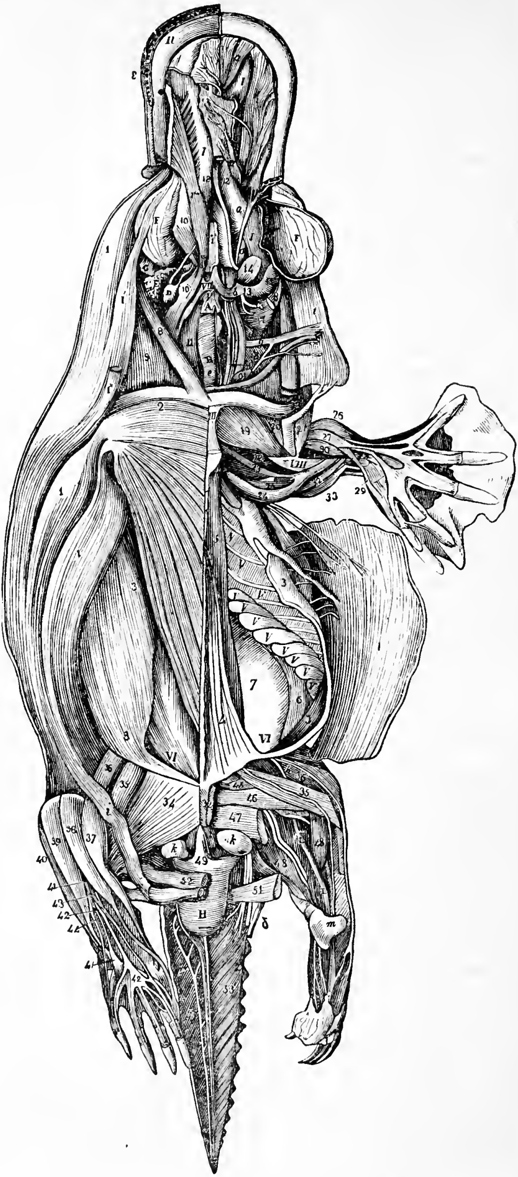
The *splenius* is united by an intermediate tendon with the opposite muscle, and is inserted into the mastoid process.

The *biventer cervicis* and the *complexus* are distinct throughout their whole course, which extends from the anterior dorsal and posterior cervical spines to the occiput; the complexus is the longest and thickest muscle, and divides into an external, shorter, and deeper-seated portion, and an internal, longer, and superficial portion.

The *sacrolumbalis* arises from the dorsal extremity of the ilium, is attached to the ribs, over which it passes in its course to its insertion into the transverse processes of the four or five posterior cervical vertebræ.

The *longissimus dorsi* is a much thicker and narrower muscle, and extends from the dorsal aspect of the sacrum along the spine to the third or fourth cervical vertebra.

Fig. 180.



Muscular system, ventral aspect. Ornithorhynchus paradoxus. (Meckel.)

The *transversalis cervicis* and *trachelo-mastoideus* are blended into a single oblong muscle arising from the anterior dorsal and the transverse processes of the six lower cervical vertebræ, and inserted into the mastoid process.

The *sterno-mastoid* is a double muscle on both sides, one portion being superficial (8), the other deep-seated; each arises separately from the episternal bone, and is separately inserted into the mastoid tubercle, behind the tympanic cavity. The *omo-hyoideus* and *mylo-hyoideus* (10, 10) have a common insertion into the os hyoides. A muscle (1″), arising from the hyoid bone and expanding to be inserted into the lower lip, serves to retract this part. The *sterno-hyoideus* (11) joins the hyo-glossus. The *genio-hyoideus* (12) and the *stylo-hyoideus* (13) have the normal relations: the *biventer maxillæ* (14) is a short thick muscle, inserted near the bend, representing the angle, of the jaw.

The caudal muscles are powerfully developed. The oblique fibres of the inferior or deflector muscles are shown at 53; they are removed on the other side to expose the anterior caudal nerves (*i*). The *obliquus externus abdominis* (3, 3) arises from all the vertebral ribs, except the first, and from the dilated extremity of the ilium; it is inserted by a strong tendon into the outer extremity of the marsupial bone (v i), then expands into an aponeurosis which is attached to the internal margin and base of the marsupial bone, and into the symphysis pubis, decussating with the tendinous fibres of the opposite muscle.

The *obliquus internus* (6) arises from the anterior part of the ilium, expands, and is inserted into the broad cartilages of the seven posterior ribs (v, v).

The *transversus abdominis* (7) is a thicker muscle, and arises from both the ilium and the transverse processes of the lumbar vertebræ; its tendon passes behind the recti to blend with that of the opposite muscle, and with the aponeurosis of the *obliqui externi*, in the linea alba.

The *pyramidalis*, or superficial rectus (4), is here, as in the ordinary Marsupials, of very large size; it arises from the whole inner margin of the marsupial bone; its fibres converge towards and are confluent at the linea alba with those of its fellow, and it gradually terminates in a point opposite the posterior part of the sternum. It depresses the ribs, shortens the abdomen, and protracts the marsupial bone.

The *rectus abdominis*, or posterior rectus (5), arises from the posterior margin of the marsupial bone, and is inserted into the cartilage of the first rib, the manubrium sterni, and the coracoid bone.

The *diaphragm* presents the structure which is characteristic of the true mammiferous animal. The lesser muscle arises from the first lumbar and four last dorsal vertebræ, and expands to be inserted into the central tendon, which chiefly receives the fibres of the greater muscle arising from the cartilages of the eleven inferior pairs of ribs.

The *pectoralis* (2) is of very striking dimensions; the origin of the superficial portion extends from the acromion, along the sternum and linea alba, almost to the pubis; a deeper-seated portion arises from the six osseous sternal ribs; the fibres of both portions converge to be inserted into the largely-developed pectoral or anterior crest of the proximal half of the humerus.

The *pectoralis minor* is attached to the coracoid, and the *subclavius* is likewise inserted, as in some other quadrupeds, into this bone, which is no longer a subordinate process of the scapula in the Monotremes.

The *subscapularis* is a narrow muscle, and narrower in reality than at first sight it appears to be, since the *supra-spinatus*, from the inflection of the spine and acromion, arises from the same aspect of the scapula, and appears to form the anterior fasciculus of the *subscapularis;* its distinct insertion into the anterior tubercle of the head of the humerus points out its true nature.

The *infra-spinatus* (20) and the large *teres major* cover the whole external surface of the scapula.

The *deltoid* is divided into an anterior and a posterior portion. The anterior portion (19) arises from the anterior extremity of the coracoid, and is inserted into the summit of the deltoid crest of the humerus: the posterior part (21) arises from the anterior and superior apex of the scapula, and is inserted into the lower half of the deltoid crest. There are also two muscles to which the name *coraco-brachialis* may be applied, a superior one (22) and an inferior one (25).

The *biceps brachii* arises by two heads; one (23) arises from the sternal extremity of the coracoid, the other (24) also arises from the coracoid; the common tendon is inserted into the middle of the radius.

The other muscles of the anterior extremity adhere closely to the mammalian type. The *extensor carpi radialis* (30) sends three tendons, to be inserted respectively into the second, third, and fourth metacarpal bones. There is a single common *flexor digitorum*, as well as *extensor digitorum* (27).

The *extensor digiti minimi* (26), the *indicator* (28), the *extensor pollicis* (29), the *pronator teres* (32), and the *flexor carpi radialis* (33) are all remarkable for their strength in the Ornithorhynchus, and are still more powerfully developed in the Echidna.

The most remarkable muscle on the palmar aspect of the fore arm is the *flexor carpi ulnaris*, which arises by two separate heads, the longer one from the broad olecranon, the shorter one from the internal condyle of the humerus; the common tendon is attached to the os pisiforme and the metacarpals of the fourth and fifth digits.

The *psoas minor* from its insertion into the pelvic arch should be regarded as a muscle of the pelvic extremity, and it is one of the largest of these muscles. It arises from the sides of five dorsal vertebræ, and its strong tendon is implanted in the remarkably-developed ilio-pectineal process. It depresses the pelvis, and with it also the tail and the pelvic extremities.

The *psoas magnus* and *iliacus internus* form a single muscle, having the usual origins, and inserted by a common tendon into the large internal condyle.

The *gluteus externus* is larger than is usually the case with quadrupeds; its tendon is inserted into the plantar fascia and the bone which supports the spur. The *gluteus medius*, *gluteus internus*, *pectineus* (45), *biceps flexor cruris*, *gracilis* (34), *sartorius* (35), *rectus femoris* (36), *adductores femoris* (46), *semitendinosus* (47), *semimembranosus*, *vastus externus*, offer no notable deviations from the usual structure. A strip of fibres (49) descends from the gracilis to the *sphincter cloacæ* (H). A muscle, called by Meckel 'flexor accessorius a caudâ ad tibiam tendens' (51), arises from the transverse processes of the anterior caudal vertebræ, and converges to be inserted into the tibia. Another peculiar adductor of the leg, which might be termed 'intertibialis' (52), is attached by its extremities to both tibiæ; its fleshy belly passes across the sphincter cloacæ (H), and is connected with a strip of the panniculus carnosus (*i*).

The *gastrocnemius* (48) derives its largest origin from the produced and expanded head of the fibula, and its smaller belly from the internal femoral condyle; its tendon is implanted in the calcaneum. The analogy between the *gastrocnemius* and *ulnaris internus* is strikingly illustrated in the Ornithorhynchus.

The *soleus* arises from the head of the fibula and from a large proportion of the tibia; it is nowhere blended with the gastrocnemius, but is inserted by a thick and short tendon into the astragalus.

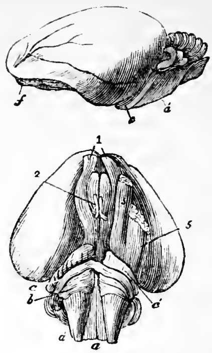
The *abductors* of the outer digits of both the hand and foot are well developed for the purpose of expanding the web which connects the toes.

In the figure the following muscles of the leg are shown, viz. 37, *tibialis anticus*, 38, *extensor hallucis longus*, 39, *peronæus longus*, 40, *peronæus brevis*, 41, *extensor digitorum communis profundus*, *brevi analogus*, 42, *extensor digitorum communis sublimis*, 43, a portion of the same muscle corresponding with the indicator of the fore leg, 44, *extensor digiti quinti accessorius*.

NERVOUS SYSTEM.

Brain. — In the male *Ornithorhynchus* Meckel found that the brain weighed two drachms, German weight (about four drachms avoirdupoise), and bore a proportion to the weight of the body as 1 to 130. It was inclosed by a pretty strong dura mater, of which the fold corresponding with the bony falx adhered but slightly to that process. The cerebrum weighed one drachm and a half, German; nearly the whole of its superficies was smooth; a few vascular impressions marked the side of the anterior lobe: its shape was triangular, depressed; the contracted anterior lobes forming the obtuse apex of the triangle: the posterior lobes are wide and cover the corpora bigemina. The surface of the cerebrum is smooth and unconvoluted (*fig.* 181).

Fig. 181.



Side view and base of brain, Ornithorhynchus. (Meckel.)

In describing the structure of the cerebral hemispheres Meckel observes, with reference to the most characteristic part of this structure in the Mammalia, "Corpus callosum adest quidem, sed breve, quam haud quatuor lineas longitudine æquet, memorabilius etiam videtur, in dimidia duo lateralia, linea mediana haud confluentia, esse disjunctum. Equidem saltem in faciebus sese spectantibus internis nullum dilacerationis vestigium invenire potui."— L. c. p. 33.

During my investigations of the structure of the brain in the Marsupial animals,* I had in memory the apparent exception to the bird-like condition of the corpus callosum, which the Ornithorhynchus, according to the above description, presented, but which each successive example of the brain of the Marsupial quadruped served to establish more firmly as the rule of structure in the higher order of the Implacental sub-class. It was difficult to believe that in the lower or Monotrematous group, the cerebral organ, which indicates so accurately the true affinities and natural position of the Vertebrate animal, and which follows so faithfully the degradation of the general organization of each species, should offer so abrupt an ascent to the cerebral condition of the placental Mammalia, as would be indicated by a corpus callosum of four lines long in a brain of which the hemispheres measure only fourteen lines in length (German scale).

The strong suspicion of an error in the celebrated anatomist's description justified a reserve in acknowledging this exception until the opportunity of testing it by a dissection of a brain of a Monotrematous quadruped should have presented itself; and my doubts as to the great development of the corpus callosum of the Ornithorhynchus were further justified by the indication of its nearer approach to the Oviparous type afforded by the simple bipartite condition of the tubercules

* Philos. Trans. 1837, p. 87.

called 'quadrigemina.' Well preserved specimens of Ornithorhynchus presented to me by Mr. Thomas Bell, surgeon R. N., in 1838, have enabled me to determine this question. There is neither corpus callosum nor septum lucidum in the Ornithorhynchus.

The part described by Meckel as the corpus callosum corresponds with the fornix and hippocampal commissure, as it exists in the Marsupialia, excepting that the essential function of the fornix, as a longitudinal commissure, uniting the *hippocampus major* with the olfactory lobe of the same hemisphere, is more exclusively maintained in the Ornithorhynchus, in consequence of the smaller size of the transverse band of fibres uniting the opposite hippocampi, and representing the first rudiment of the corpus callosum, as it appears in the development of the placental embryo. The thin internal and superior parietes of one lateral ventricle are wholly unconnected with those of the opposite ventricle.

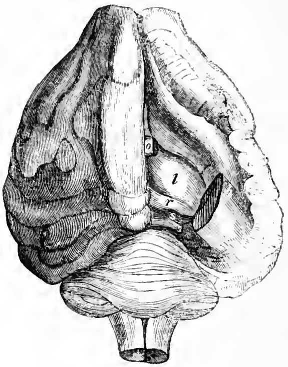
Meckel makes no mention of the fornix or hippocampus major: the latter forms a large pyramidal prominence at the outer and posterior part of the ventricle, and is confluent with the inferior and external parietes of that cavity. The corpus striatum is long and narrow: the thalamus opticus small, and is united with its fellow by a soft commissure, which rises to the same level, whereby they appear to form a continuous body. The anterior commissure is very large, as in the Marsupials. The posterior bigeminal body is much smaller than the anterior, and the transverse depression which divides them is very feebly marked: the longitudinal groove is equally feeble on the 'nates,' and is altogether absent in the 'testes,' which thus form a single small tubercle. It is in the condition of these parts, recognized, but too briefly noticed by Meckel, that the brain of the *Ornithorhynchus* deviates most essentially from the Marsupialia, and offers the most direct step in the descent to the Oviparous type.

The cerebellum is moderately large, highest in the middle, but with small lateral appendages: the median or vermiform part is traversed by transverse furrows; and its vertical section exhibits an 'arbor vitæ.'

The medulla oblongata is broad and depressed: its inferior surface exhibits the corpora pyramidalia (*fig.* 181, *a*), the corpora olivaria (*a'*), which expand as they advance forwards, apparently in relation to the immense size of the trigeminal nerve. Their anterior extremities are crossed by large trapezoid bodies (*b*), (figured by Meckel as the pons Varolii); and anterior to those is the true 'nodus encephali' (*c*), which is narrow, in correspondence with the small lateral lobes of the cerebellum; and from this there emerges on each side a large ganglioid body (*c'*), from which the trigeminal nerve (5) arises. The under surface of the medulla oblongata is traversed by a deep median longitudinal groove.

The brain of the Echidna is relatively larger, and its external surface is complicated by convolutions.* It weighs twelve drachms and thirty grains avoirdupoise, and bears a proportion to the weight of the body as 1 to 50. The cerebral hemispheres conceal the bigeminal bodies, but do not extend over the cerebellum. The broad posterior part of each hemisphere is disposed in three nearly parallel transverse convolutions, the outer extremities of which

Fig. 182.



Brain of the Echidna, right hemisphere dissected. (Original.)

incline forwards (*fig.* 182); anterior to these is a larger convolution bent upon itself at a right angle, one crus running transversely; the other longitudinally, and forming the inner boundary of the anterior half of each hemisphere: this convolution was not divided by a transverse anfractuosity, as in the figure in the 'Voyage de la Favorite,' loc. cit. On the outside of the longitudinal convolution there are two or three oblique folds which converge towards the contracted anterior part of the brain, or descend to its under surface: besides these principal and more constant convolutions there are a few smaller and less regular ones at the lateral and inferior parts of the hemispheres, especially on the great natiform protuberances. The principal anfractuosities sink more than a line's depth into the substance of the hemisphere: the posterior convolutions are continued upon the median surface of the hemisphere, and interlock with those of the corresponding hemisphere. The depth of the median fissure of the hemispheres is from five to six lines: the hippocampal commissure (*o*) one line and a half in antero-posterior diameter is seen at the bottom of the fissure which divides the hemispheres.

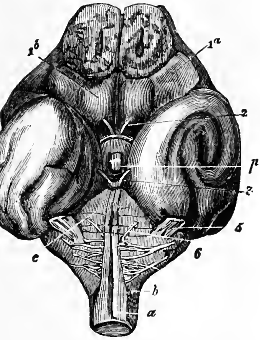
The dura mater in the Echidna is thin and

* See the figures and description of the external characters of the brain of the Echidna, given by MM. Eydoux and Laurent in the 'Voyage de la Favorite,' 8vo. 1839, tom. v. pl. 9, p. 161.

transparent; the membranous falx is less deep than the osseous one of the Ornithorhynchus. I found no bony plate between the hemispheres in the Echidna. The arachnoid is transparent, but relatively strong. The cerebellum is traversed by several narrow transverse anfractuosities, disposed as in *fig.* 182. The vermiform or median lobe, as in the Ornithorhynchus, is larger in proportion to the lateral lobes than in the Marsupialia, and the limits between them are much less distinctly defined.

The base of the brain in the Echidna (*fig.* 183) is remarkable for the deep and wide excavations at the under part of the anterior

Fig. 183.



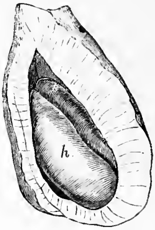
Base of brain of Echidna. (Original.)

lobes, forming the base of the enormous olfactory nerves. The natiform protuberances are unusually large. The medulla oblongata is broad and flat, but contracted anteriorly to an angle; the pyramidal bodies (*a*) long and narrow; the olivary bodies (*b*) broad, but flat. The pons Varolii (*c*) presents, as in the Ornithorhynchus, a low development proportionally to the size of the brain: it is not raised beyond the level of the under surface of the medulla oblongata: it is of a triangular form with the obtuse apex turned forwards: the median longitudinal groove formed by the basilar artery is well marked: the trapezoid bodies are relatively narrower than in the Ornithorhynchus.

The pituitary gland (*p*, *fig.* 183) is one line and a half in length and one line in breadth: its under surface adheres closely to the dura mater of the sella turcica. The corpus mammillare is single, broad, and but little elevated.

The internal, superior, and posterior walls of the lateral ventricle are from one line to two lines in thickness; the outer wall is between two and three lines; when the roof of the ventricle is removed, as in *fig.* 184, two elongated convex bodies are exposed, as in the marsupial brain: the posterior and largest (*h*) is the hippocampus major: the anterior body (*s*) is the corpus striatum. The whole internal wall of one ventricle is quite disunited from that of the opposite hemisphere.*

Fig. 184.



***Right lateral ventricle laid open, Echidna.* (*Original.*)**

The contracted anterior parts of the hippocampi are connected together by the short transverse commissure above mentioned, which is the sole representative of the corpus callosum and fornix. The septum lucidum and fifth ventricle are entirely absent.

The pia mater, which accompanies the ventricular artery into the floor of the ventricle, at the base of the hippocampus, spreads over the optic thalami, and sends upwards a smooth fold of membrane, one line and a half broad, between the hippocampus and the corpus striatum. The free margin of this fold is slightly thickened by the choroid artery.

It is necessary to remove the hippocampus and posterior part of the hemisphere, in order to bring into view the optic thalami and bigeminal bodies.

The optic thalami (*fig.* 182, *l*) and nates appear as one convex body slightly contracted laterally, and divided from each other by a sigmoid linear fissure: the testes are only half the breadth of the nates, and the median longitudinal line of division, which is very faint in the larger bodies, is not visible in the smaller and posterior tubercle. The Echidna corresponds in this characteristic modification with the Ornithorhynchus.†

* The internal structure of the hemispheres of the Echidna's brain is not described in the 'Voyage de la Favorite.'

† MM. Eydoux and Laurent have thrown into the following tabular form the published results of the dissections of the brains of the Implacental Mammalia as compared with Placental Mammals and Birds.

They add: "En indiquant ce résultat des observations de M. R. Owen, aux-quelles nous avons joint les observations de Meckel en les rectifiant, nous devons faire remarquer que Meckel a cepen-

The medullary fibres of the optic thalami (*fig.* 182, *t*) and bigeminal bodies (*r*, *s*) form a thin stratum above a third ventricle of unusual capacity, the relative size of which appeared somewhat larger than was natural from the decomposition of the medullary matter of the soft commissure. The principal commissure of the hemispheres is the anterior one, which is subcylindrical, and measured two lines thick vertically, and one and a half horizontally. The posterior commissure is a narrow strip of medullary matter, which thickens the upper part of the valvula Vieussenii. The 'iter' or canal from the third to the fourth ventricle is proportionally wide. The arbor vitæ, as displayed by a vertical section of the vermiform process, sends off four principal and some minor medullary branches.

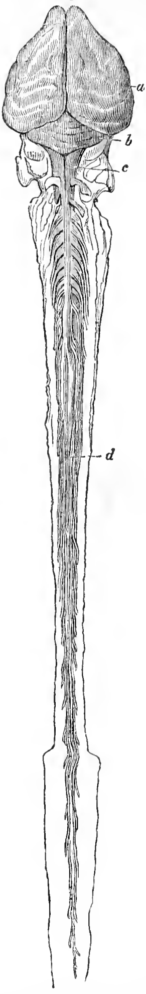
The spinal chord in the Ornithorhynchus is long and slender, but fills closely the spinal canal: it is thickest at its commencement and at the lower two-thirds of the cervical region; it is more slender in the dorsal region, especially near the loins; it is slightly enlarged in the lumbar region, and gradually terminates in a point in the canal of the sacral vertebræ: the cauda equina is very feebly represented.

In the Echidna the form and proportions of the spinal chord (*fig.* 185) are strikingly different: it is here nearly as short and thick, relatively, as in the hedge-hog, and terminates in a point, at *d*, before it has reached the middle of the dorsal region. Nevertheless, in this short tract the two usual enlargements, giving origins respectively to the nerves of the pectoral and pelvic extremities, are clearly marked; the slightly contracted intermediate portion being extremely short: the cauda equina is remarkable for its length. The nerves escape, as usual, from the intervertebral foramina, and have a longer course in the spinal canal, in proportion as they supply parts more distant from the chord.

It is interesting to find the peculiar structure of so important a part as the spinal chord repeated in two species, which, with the exception of the dermal spines, and their common characters as Mammalia, differ in other respects as widely from one another, and occupy such distant places in their class. Can the shortness of the solid chord, and the great length of the nerves within the spinal canal, have any physiological relation with the habit, common to both the placental and monotrematous hedgehogs, of rolling the body into a ball when torpid or asleep, or when the tegumentary armour is employed in self-defence?*

The olfactory nerves are large in the Ornithorhynchus (*fig.* 181, 1, 1). The external root

Fig. 185.



Brain and spinal chord, Echidna, Half natural size. (Original.)

is remarkable for its length and relative size: it arises from the posterior surface of the cerebral hemisphere immediately behind the bigeminal body; bends round the crus cerebri to the inferior surface; and is continued forward to join the internal root which rises from the base of the anterior lobes of the brain.

In the Echidna the olfactory nerves may be described as enormous. The external root (*fig.* 183, 1 *a*) arises from nearly the whole anterior part of the natiform protuberance, which extends its origin, as in the Ornithorhynchus, to the posterior part of the hemisphere. The internal root (183, 1 *b*) is also very large: the lateral ventricle is prolonged forwards into the olfactory nerve, which would appear like a continuation of the entire hemisphere, were it not that it is overlapped by the anterior convolution.

The extent and complications of the olfactory cavity are proportionate in the two Monotremes to the size of their respective nerves.

The optic nerve (*fig.* 181, 183, 2) is small in both Monotremes, in accordance with the diminutive size of the eye: the two nerves are joined by a transversely oblong chiasma.

The eye is protected, in the Ornithorhynchus, by a cartilaginous plate continued from the upper part of the orbit, which Meckel compares with the bony palpebral plates in the Crocodile. Both Monotremes have a well developed membrana nictitans: there are also an upper and a lower eyelid, each of which has its proper apertor muscle.

In the Ornithorhynchus the sclerotic is cartilaginous, the cornea flabby, the retina very thick: there is no trace of pecten or marsupium: the lens is very small, two lines in vertical and transverse diameter, one line in antero-posterior diameter; the anterior surface

dant admis, dans les figures relatives à l'encéphale de l'ornithorhynque l'existence du corps calleux; mais, en étudiant avec soin l'encéphale de notre échidné, nous nous avons reconnu que les descriptions de M. R. Owen sont plus exactes que celles de Meckel, et que les déterminations de l'anatomiste Anglais doivent etre adoptées." — *Voyage de la Favorite*, p. 166.

* "Cet échidné passait la majeure partie de son temps dans une espèce d'engourdissement, blotti, enroulé à la manière des hérissons." — *Voyage de la Favorite*, p. 159.

is nearly flat, the posterior very convex. The choroid is black, without a tapetum lucidum: the pupil is circular.

The nerves of the third pair (*fig.* 183, 3) have the usual origin and destination, and are likewise very small: the fourth nerve is still more minute.

The fifth pair in the Ornithorhynchus exceeds, in relative magnitude, that of any other animal; though large, also, in the Echidna, its size is much less remarkable in this Monotreme.

The trigeminal nerve in the Ornithorhynchus, (*fig.* 181, 5,) emerging from the ganglion anterior to the pons, soon divides into three branches; the first and second appearing as one. The first and smallest division divides into two equal branches: the superior or ethmoidal branch enters the nose, emerges from a canal in the upper part of that cavity, and supplies the skin at the upper part of the face; and, by a branch continued from between the nasal and intermaxillary bones, is distributed to the nostrils and contiguous integument.

The second division of the fifth is two lines broad and one line and a half thick; it passes through the foramen rotundum, and the chief part of it passes into the ant-orbital canal. On its emergence it divides into two branches, distributed, the one to the nasal or upper parietes of the face, the other to the lateral or labial integuments. The palatine branch divides into a posterior smaller nerve, which passes through the posterior palatine foramina: the anterior and larger branch emerges from the anterior palatine canal and supplies Jacobson's organ and the surrounding palatine membrane.

The third division of the fifth (5′) is broader but thinner than the second; it leaves the cranium by the foramen ovale, and is distributed as usual, in part to the manducatory muscles, but mainly to the sensitive labial integument of the lower jaw (*fig.* 180, *a a*).

The sixth nerve (*fig.* 183, 6) is as small as the third. The seventh and the acoustic present half a line in diameter.

The acoustic nerve is expended upon a labyrinth remarkable for the small relative size of the semicircular canals, and their free projection into the cavity of the cranium.

The cochlea is wide, but not high; it is bent around a modiolus, and divided as usual into a superior and inferior scala.

The foramen ovale is nearly circular, and opens into the wide but shallow tympanic cavity. It is naturally closed by the base of a small columelliform and imperforate stapes (*fig.* 173, D, *d*): the stem of this ossicle is articulated with a triangular plate of bone (*c*), representing, according to Meckel, the incus. This bone is connected with a small bent osseous style (*b*), which serves to complete, with the similarly-shaped tympanic ossicle (*a*), the frame supporting the membrana tympani. This membrane is concave externally, and forms the inner extremity of a long and narrow meatus auditorius externus, which is strengthened by a cartilaginous incomplete cylinder, protected by a valve, but not provided with an external auricle.

The auricle is equally wanting in the Echidna, in which the external aperture of the auditory canal presents the form of a vertical slit, shaped like the italic *S*, one inch and a half in length: the margins of the slit are tumid, and support a row of bristles which protect and cover the orifice when recumbent. The meatus is remarkably long; the tube is strengthened in this Monotreme by a series of incomplete cartilaginous hoops, connected together by a narrow longitudinal cartilaginous band, so that its structure closely resembles that of a trachea (*fig.* 188, *a*, *a*). The tympanic fossa is almost entirely encircled with a slender hoop of bone (*fig.* 169, c) consisting of the anchylosed tympanic bone and malleus.

The portion which represents the tympanic bone (*a*), and which can be separated from the malleus in the young subject, is a slender osseous filament bent into three-fourths of a circle, and placed upon the inner margin of the tympanic fossa, its concavity looking outwards: this concavity is impressed with a fine groove for the insertion of the membrana tympani: the posterior part of the hoop passes across the commencement of the Eustachian canal, and terminates in a free point upon the posterior wall of the tympanic fossa: the anterior end of the hoop is applied to and usually anchylosed with the longitudinal bar of the malleus (*b*).

Only a small portion of this ossicle is contained within the cavity of the tympanum; the principal portion forms the external and part of the posterior boundary of the bony meatus auditorius, and is then continued forwards in the form of a slender pointed process; the bone slightly expands as it extends backwards, and its broadest part is abruptly bent inwards until it nearly meets the posterior end of the tympanic hoop. From the extremity of this inflected portion a slender compressed process (*c*) extends to the centre of the space encircled by the bony hoop; it is attached by its whole length to the membrana tympani, and represents the handle of the malleus. At the posterior margin of the broad incurved part of the malleus there are two minute tubercles nearly a line apart: the short and simple columelliform stapes (*d*) ascends vertically from the innermost of these tubercles, with the upper surface of which it is articulated; its opposite extremity closes the foramen ovale in the form of an expanded plate. The membrana tympani is concave outwardly at its middle part.

The eighth and ninth pairs of nerves have the usual origins and proportions. The pneumogastric nerve (*fig.* 180, *d*) is closely attached, at its origin, to the hypoglossal (*fig.* 180, *b*), but is quite distinct from the sympathetic (*fig.* 180, *f*): it gives off the superior laryngeal, and then proceeds along the neck to the chest: the right nerve here sends its recurrent branch, in the usual manner, round the arteria innominata; the left branch (*fig.* 187, *k*) winds round the aorta: the trunk of the pneumogastric is then expended in the cardiac, pulmonic, œsophageal, and gastric nerves. The spinal accessory nerve (*fig.* 180, *c*) is thicker than the pneumogastric, and has the usual distribution.

The brachial plexus is formed by the five posterior cervical and the first dorsal nerves. The third cervical nerve is shown at *g*, *fig.* 180. The median nerve perforates the inner condyle of the humerus.

The lumbar plexus is formed by the two posterior dorsal, the two lumbar, and the first sacral nerve.

The great ischiadic nerve divides into the peroneal and tibial branches before it quits the pelvis. The crural nerve is shown at *h* (*fig.* 180).

DIGESTIVE SYSTEM.

The Ornithorhynchus, which subsists on aquatic insects, larvæ, mollusks, and other small invertebrates which conceal themselves in the mud and banks of rivers, is provided with a mouth which most nearly resembles the flat and sensitive bill of a lamellirostral bird. The singularly modified jaw-bones, already described, are invested by a smooth coriaceous integument, (*fig.* 173, A, E, *a*,) devoid of hair, but perforated by innumerable minute foramina. At the base of the jaws this integument is produced into a free fold, which overlaps the hairy covering of the cranium immediately behind it. The integument covering the upper mandible extends beyond the margins of the bone, and forms a tumid, smooth, and highly sensible lip; the narrower and shorter under jaw is more closely invested: the oral or upper surface of the lateral part of the under jaw supports a series of about twenty nearly transverse folds, increasing in breadth as they approach the angle of the jaw: the corresponding surface of the upper jaw is smooth.

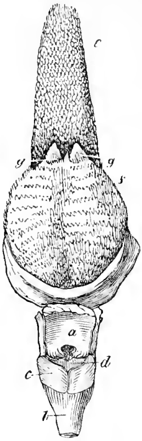
The two anterior horny teeth in both jaws are elongated, narrow, with their outer part raised into a trenchant edge in the lower jaw. The two posterior teeth (*fig.* 173, *h*, and F) in both jaws are flat, with two broad and slight excavations, corresponding with the two parts into which each molar may be divided in the young animal.

Immediately on the outside of the posterior part of each molar in the lower jaw, is the orifice of an oblong cheek-pouch (*fig.* 180, F, F), about two inches in length, and half an inch in diameter: the pouch is continued backwards, and is lined with a hard dry cuticle.

The tongue (*fig.* 186) consists of two parts, the normal, anterior, narrower portion (*e*), and a broad, raised posterior lobe (*f*), analogous to the intermolar eminence of the tongue in certain Rodents. This part is produced anteriorly into a free projecting apex in the Ornithorhynchus, and is rendered still more remarkable in that animal by being armed with two short thick horny spines (*g*, *g*), projecting forward.

The anterior part of the tongue is beset with rather coarse papillæ, and extends into the posterior interspace of the incisive teeth, but with the apex more than an inch distant from the anterior aperture of the mouth. The raised posterior lobe of the tongue must impede the passage of unmasticated food to the pharynx, and doubtless tends to direct it on each side into the cheek-pouches; whence the Ornithorhynchus may transfer its store at leisure to the molar teeth, and complete its preparation for deglutition. An air-breathing warm-blooded animal, which obtains its food by the capture of small aquatic animals, while submerged, must derive great advantage from the structure which enables it to transfer them quickly to a temporary receptacle, whence they may be extracted and masticated while the animal is floating on the surface or at rest in its burrow.

Fig. 186.



Tongue and larynx of the Ornithorhynchus. (*Meckel.*)

The soft palate is thick, broad, and divided posteriorly into three fimbriated lobes.

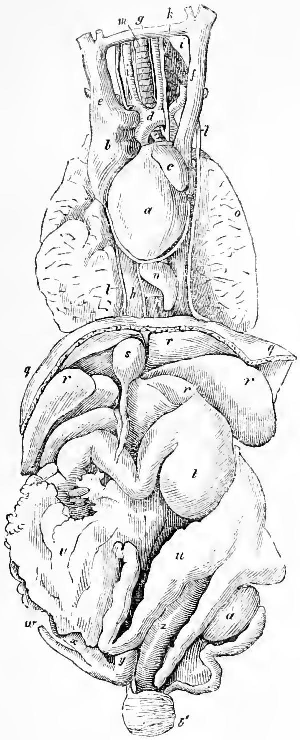
The pharynx is narrow, and is singularly encompassed by two posterior processes of the thyroid cartilage (*fig.* 189, *c*, *c*).

The œsophagus becomes slightly dilated near the diaphragm, below which it expands into a moderate-sized membranous stomach (*fig.* 187, *l*), which is chiefly remarkable for the close approximation of the cardiac and pyloric orifices. The intestinal canal is moderately wide, five feet three inches and a half in length, and provided, at a distance of four feet three inches from the pylorus, with a small and slender cœcum (*w*).

The small intestines are chiefly remarkable for the extent of the mucous coat, which is disposed in numerous folds or valvulæ conniventes: these are transverse at the beginning of the duodenum, but are placed more or less obliquely in the rest of the small intestine; they are about two lines broad, and placed very close together in the duodenum, but diminish in breadth and number as they approach the cœcum coli. There are about fifteen longitudinal folds in the first half of the colon; the remainder of the intestine has a smooth inner surface. There is no valvula coli. The rectum (*z*) terminates at the anterior and dorsal part of the vestibular compartment of the cloaca. In *fig.* 191 a probe (*b*′) is passed through this termination. On each side of its termination there is an oblong glandular prominence, about four lines in length and two in breadth, on which there are about ten orifices of glands, which Meckel considers as analogous to the anal glands of other quadrupeds.

The long, slender, tubular mouth of the

Fig. 187.



Thoracic and abdominal viscera, Ornithorhynchus. (*Meckel.*)

Echidna is unprovided with teeth; but the palate is armed with six or seven transverse rows of strong, sharp, but short retroverted spines. The tongue is long and slender as in the true Anteaters; its dorsum is broad, flat, callous, and beset with hard papillæ, and the insects are doubtless crushed and lacerated between these and the palatal spines. As, however, the food undergoes less comminution in the mouth of this Monotreme than in that of the Ornithorhynchus, the pharynx and œsophagus are wider, and a dense epithelium lines the inner surface of the latter tube, and is continued over the capacious stomach to the pylorus, near which orifice it is developed into numerous horny and sharp papillæ. The subjacent mucous membrane is smooth; the tunics of the stomach are very thin, except at the pylorus, which forms a prominent protuberance in the duodenum. The intestinal canal of the Echidna is seven times the length of the body; the mucous membrane is not raised into valvular folds; a small vermiform and glandular cœcum divides the small from the large intestines; the rectum terminates as in the Ornithorhynchus.

Salivary glands.—There appears to be no parotid gland in the Echidna, and it is doubtful whether the thin flat stratum of glandular substance (*fig.* 180, *E*), which extends from the meatus auditorius to the check-pouch in the Ornithorhynchus, can be so regarded. The submaxillary gland (*fig.* 180, *D*) is a moderately-sized, oval, compact body, situated behind and below the meatus auditorius; it measured five lines in the long diameter and four in the short diameter. The duct is very small, scarcely admitting an absorbent injecting pipe; it passes under the omo-mylo-hyoideus (10), and then, contrary to the usual mode, begins to be disposed in a series of about twelve close transverse folds, and terminates by a single aperture at the frænum linguæ.

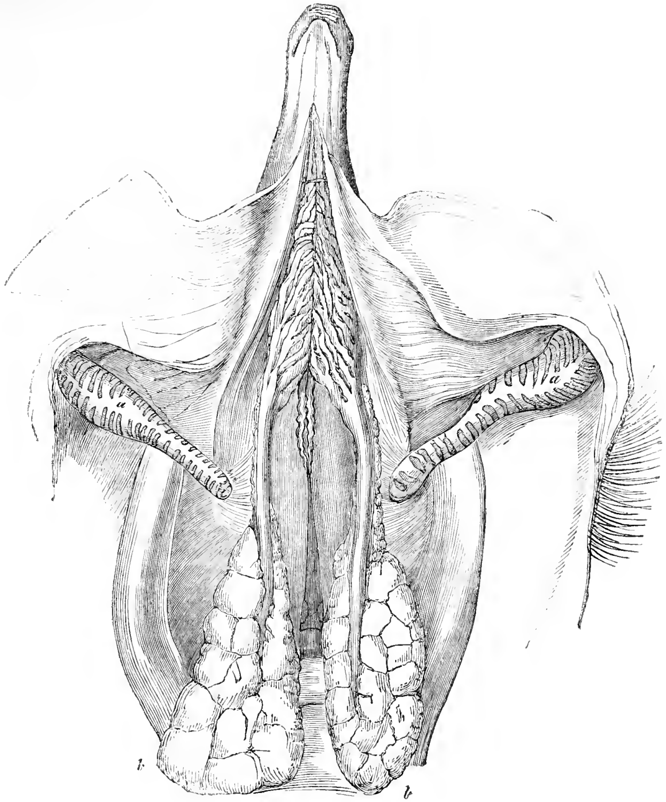
The submaxillary gland (*fig.* 188, *b*) is of unusual dimensions in the Echidna, in which it extends from the meatus auditorius along the neck, and upon the anterior part of the thorax: it is a broad, flat, oblong lobulated body, narrowest at its anterior extremity, from which the wide duct emerges. When the duct has reached the interspace of the lower jaw it dilates, and then divides into eight or ten undulating branches, which subdivide and ultimately terminate by numerous orifices upon the membranous floor of the mouth. This modification, which escaped the observation of Cuvier and M. Duvernoy, appears to be unique. The large size of the glands and the mode in which the secretion is spread over the floor of the mouth, relate to the lubrification of the long, slender, and extensible tongue, and to its fitness as an instrument for obtaining the insect food of the Echidna.

The *liver* (*fig.* 187, *r*, *r*) closely retains the mammalian type of the organ in both Monotremes. Four lobes may be distinguished in the Echidna: the principal or cystic lobe receives the suspensory ligament in a fissure; the large gall-bladder is placed a little to the right; the left lobe occupies the left hypochondrium; the Spigelian lobule is of moderate size; it is an appendage of the right lobe. The liver presents nearly the same form in the Ornithorhynchus, which has likewise a large gall-bladder (*fig.* 187, *s*).

There are three hepatic ducts in the Echidna which join the cystic, and the common canal terminates in the duodenum rather more than an inch from the pylorus. In the Ornithorhynchus the two chief hepatic ducts join the cystic near the neck of the bladder; the third hepatic joins a more distant part of the cystic; the ductus choledochus receives the pancreatic duct about nine lines before its termination, as in the Marsupials, where its coats are thickened and glandular, and opens into the duodenum about eight lines from the pylorus.

The *pancreas* in the Ornithorhynchus is a thin lobulated gland bent upon itself; the left and larger portion descends by the side of the left

Fig. 188.



Submaxillary glands, Echidna setosa (*Original.*)

lobe of the spleen.* The pancreas is thicker in the Echidna, and enlarges considerably towards the duodenum.

The principal difference occurs in the place of termination of the pancreatic duct, which, in the Ornithorhynchus, joins the ductus choledochus, but in the Echidna terminates separately in the duodenum and nearer the pylorus than does the ductus choledochus.

The arrangement of the hepatic and pancreatic ducts is thus conformable to the Mammalian type, and the Ornithorhynchus, in the place of the junction of these ducts near the commencement of the *ductus choledochus*, manifests its affinity to the Marsupials, as the same structure occurs in the Dasyure.

The *spleen* (*fig.* 187, *u, u*) consists of two lobes bent upon each other at an acute angle, in which the Monotremes again resemble the Marsupials. In the Ornithorhynchus the anterior and right lobe is four inches long, the posterior and left lobe two inches and a half; the right lobe is bent upon itself. In the Echidna, besides the two lobes which are continued forwards from the left side, there is a third shorter descending appendage.* The lobes are thin and moderately broad in both Monotremes, and in structure, size, situation, and general figure, the spleen conforms to the Mammalian type, although this is exhibited under a more than usual complication of external form.

CIRCULATING SYSTEM.

Blood of the Ornithorhynchus.—A Mammal presenting such striking resemblances in certain parts of its organization to the oviparous

* Meckel, loc. cit. p. 46.

* Cuvier, l. c. t. iv. p. 591.

modification of the Vertebrate type as does the Ornithorhynchus, is one of which it was obviously most interesting to ascertain the form of the blood-discs. I have made applications to different professional and zoological correspondents in Australia on this subject, for the transmission of a portion of recently drawn blood thinly spread and dried on glass, or preserved in its fluid state in brine and other menstrua of the same density as serum, and for the results of observations on the blood-discs of both the Ornithorhynchus and Echidna. Mr. Hobson, of Hobart Town, Van Diemen's Land, an accomplished surgeon and comparative anatomist, has made the required observations on the blood of the Ornithorhynchus, of which he has transmitted to me the following account:—"The globules of the blood of the Ornithorhynchus are discoid, and measured about the $\frac{1}{3000}$th of an inch, calculating two-and-a-half millimetres to the line. The human blood-globules were placed side by side with those of the Ornithorhynchus, and both in shape and size so nearly resembled each other that it was impossible to say which was human and which was Ornithorhynchus. These examinations were made in the presence of Mr. Ronald Gunn, by means of one of Oberhauser's microscopes; the powers used were 250, 400, and 800. In order to be sure that there was no delusion, I placed the elliptical globules of a Lizard's blood beside those of the Ornithorhynchus. The tenacity and high florid colour of the blood, together with the greater proportional number of globules in a given quantity" (in the Ornithorhynchus) "is most interesting in an analogical point of view."

From the preceding highly valuable observations we may infer that the *Ornithorhynchus* resembles the Mammalia in the circular form, the size, the proportional number, and florid colour of its blood-discs, which correspond in size with those of the only Edentate species yet examined, viz. the Armadillo,* and consequently with those of the Quadrumana and of Man.

The blood-discs of the Echidna, according to the observations made by Dr. John Davy on a portion of blood of that animal, transmitted to England in brine, are likewise circular.

Heart.—The heart of the Ornithorhynchus (*fig.* 187, *a*, *b*, *c*) presents a rounded oblong form; it is situated in the middle of the anterior part of the chest, parallel with the axis of the cavity. It is inclosed in a thin subtransparent but strong pericardium.

The right auricle (*b*) is larger and longer than the left; its appendix is free and is slightly bifid, as in the Marsupials. It receives the venous blood, also, as in that order, by three great veins; the left vena innominata (*f*) descending behind the left auricle to join the termination of the inferior cava (*h*). The coronary vein also terminates in the auricle to the right of the inferior cava. The right superior cava (*e*) is joined to the left by a transverse branch (*g*). Meckel found in the heart of both the Ornithorhynchi dissected by him a deep but closed fossa ovalis, near the upper extremity of the septum. This structure would indicate that the intra-uterine existence of the young was of longer duration than in the Marsupialia.

The right ventricle (*a*) is capacious, with thin parietes. The tricuspid valve I found to consist of two membranous and two fleshy portions: the smallest of the latter was situated nearest the origin of the pulmonary artery, and seemed to correspond with the lesser fleshy valve observable in the heart of certain birds, as the Ostrich; it is attached to the whole of the side of the first or adjoining membranous portion. The second fleshy portion may be described as analogous to the muscular valve in the Bird's heart, if the lateral margin of this were detached from the wall of the ventricle, and the connection of its two extremities was preserved, the one to the angle between the fixed and moveable wall of the ventricle, the other to the auriculo-ventricular orifice. The two edges of the lower half of the second fleshy portion of the valve in the Ornithorhynchus are free; but those of the upper half are attached to the two membranous portions of the tricuspid valve; the margin of the membranous part of the valve is attached to the fixed wall of the ventricle by two small chordæ tendineæ; and the structure of the valve thus offers an interesting transitional state between that of the Mammal and that of the Bird.*

The origin of the pulmonary artery is provided with the three usual sigmoid valves.

The left ventricle has very thick parietes, which form the apex of the heart; the mitral valve is membranous; the larger flap is attached to two strong columnæ carneæ; the smaller flap to three smaller columnæ.

The small left auricle (*c*) receives two pulmonary veins.

In the Echidna the free appendix of the right auricle is slightly indented. The terminal orifice of the superior cava is protected by a membranous semilunar valve, extending from its left side. The musculi pectinati diverge from a strong fasciculus, which extends from the appendix to the orifice of the inferior cava; this fasciculus bounds the left side of a wide fossa ovalis, which is imperforate. The inferior cava is protected by a large membranous Eustachian valve; the left vena innominata terminates by a distinct aperture to the left of the preceding, and is also defended by a process of the Eustachian valve. The inner surface of the right ventricle is more irregular than in the Ornithorhynchus; the free wall is attached to the fixed one by several columnæ carneæ and short chordæ tendineæ; the tricuspid valve is membranous and consists of one principal portion attached to the exterior

* See Medical Gazette, Nov. 18, 1840.

* "Similitudo quædam cum avium valvula venosa dextra et propter carnositatem et propter figuram minime prætervidenda adest."—*Meckel*, l. c. p. 31.

circumference, and a smaller portion closing the outer angle; the free margin of the valve is attached to the extremity of a large fleshy column, arising by different roots from both the fixed and the free walls of the ventricle; a short fleshy column is attached to the left extremity of the valve; some chordæ tendineæ are fixed to the right angle of the valve. The rest of the structure of the heart corresponds with that in the Ornithorhynchus.

The aorta (*fig.* 187, *d*) bends, as in the Mammalia, over the left bronchus. The primary branches come off from the arch, in both Monotremes, as in Man, viz. arteria innominata, left carotid, and left subclavian. The innominata divides, after a course of three lines, into the right subclavian and carotid (*fig.* 187, *i*), the latter being the smallest branch. Both subclavians emerge from the thorax above the first rib, and pass between it and the coracoid.

The phrenic, cœliac, and mesenteric arteries are given off from the abdominal aorta; the renal artery is short, wide, and single; there is no inferior mesenteric artery, but the abdominal aorta terminates by dividing into the two common iliac and the caudal arteries, the arterial system agreeing in this and the other essential characters with the Mammalian type. The crural artery is shown at *y*, *fig.* 180.

Each of the superior venæ cavæ receives the azygos vein of its respective side. The inferior cava has a long course in the thorax; it is greatly dilated in the liver in the Ornithorhynchus, as it is in the Placental divers, the Otter and Seal for instance.*

The veins of the kidney are continued from the renal artery, and communicate solely with the inferior cava. The vena portæ is constituted as in other Mammalia.

RESPIRATORY SYSTEM.

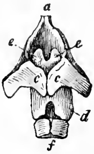
The *lungs* of the Monotremata are confined to the thoracic cavity, and suspended freely in compartments partitioned off by duplicatures of the pleura. The right lung is divided, in the Ornithorhynchus, into three lobes, of which the smallest (*fig.* 187, *n*) fills the interspace between the heart and diaphragm: the left lung (*o*) is undivided. The structure of the whole is spongy, and divided into minute cells.

The *trachea* (*fig.* 187, *m*) is wide, as in most aquatic mammals: the cartilaginous rings, fifteen in number, are broad and slightly overlap each other: the bronchial annuli are bony, and are continued of that texture through a great part of the lungs.

In the Echidna the trachea is narrower than in the Ornithorhynchus: there are twenty-two tracheal hoops, which are disunited behind; very firm cartilaginous annuli are continued along the larger branches of the bronchus for some way into the lung, but the smaller branches are membranous.

There is no trace of inferior larynx in either Monotreme. The superior *larynx* is conformable to the Mammalian type, but presents some remarkable modifications in the Ornithorhynchus. The thyroid cartilage (*fig.* 189, *c*) in this animal is very broad; its middle part is prominent and acuminate: the lateral alæ are bony, and each of them divides, and sends one of the processes to the posterior part of the pharynx (*fig.* 186, *c*), where it becomes cartilaginous, and is confluent with the corresponding process of the opposite side. The cricoid cartilage (*fig.* 189, *d*) is ossified at its middle anterior part. The arytenoid cartilages, (*fig.* 189, *e*, *e*) present the usual triangular form, and are of large size. The epiglottis (*fig.* 189, *a*) is remarkably broad, with an acuminated and notched apex.

Fig. 189.



Larynx of Ornithorhynchus. (*Meckel.*)

Besides a small thymus gland, Meckel found in the Ornithorhynchus two other lateral glands on the external part of the chest, extending between the scapula and humerus, covered only by the panniculus carnosus and the trapezius. These presented a reddish colour, a lobulated structure, and pretty firm texture.

RENAL SYSTEM.

The *suprarenal bodies* (*fig.* 190, *b*, *b*) are of moderate size, of the usual structure, and have the ordinary situation internal to the anterior extremities of the kidneys.

The *kidneys* (*a*, *a*), in both Monotremes, are smple, compact, conglobate glands, situated, as usual, far forwards on the loins, the right a little in advance of the left. The external surface, after the removal of the capsule, is smooth. The renal tissue consists of the two usual portions; the cortical, or softer and more vascular part, being easily distinguishable from the more compact medullary part. The tubuli uriniferi terminate on the concave surface of a small and simple pelvis.

The ureter (*fig.* 190, *c*, *c*) takes the usual course to the contracted neck of the bladder, but terminates, in the male, in the urogenital canal, below the vasa deferentia; and, in the female, (*fig.* 191, *l*, *l*,) beyond the uterine orifice, which thus intervenes between the ureter and the orifice of the urinary bladder.

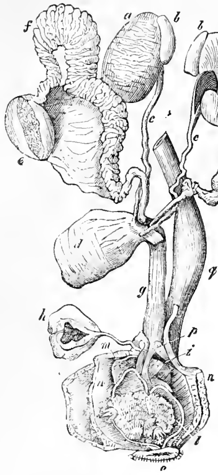
In all respects, save the place of termination of the excretory ducts and their relation to the reservoir of the renal secretion, the Monotremes adhere closely, in regard to their urinary system, to the Mammalian type. The circumstances in which they deviate from the higher mammals approximate them closely to the Reptilia, and especially the *Chelonia*; and it is to be observed that the deviation commences where the urinary system begins to be connected with the generative organs, in which the oviparous type of structure is especially manifested.

ORGANS OF GENERATION.

The *male organs* in both Monotremes consist of a testis, vas deferens, Cowper's glands, and penis: there are neither prostatic glands nor vesiculæ seminales.

* Meckel, l. c. p. 32.

Fig. 190.



Male organs, Ornithorhynchus. (*Meckel.*)

The Monotremes are true *testiconda*, and in this respect differ from the Marsupial animals. In the Echidna each testicle is situated immediately below, or sacrad of, the kidney, and is suspended to that gland by a fold of peritoneum; the same fold is continued to the neck of the bladder, inclosing the vas deferens, which is disposed in a series of close transverse folds throughout its whole course. It corresponds closely, in these respects, with the Ornithorhynchus. In neither Monotreme is there any disparity of size between the right and left testicle: the latter is figured *in situ* at *a'*, *fig.*187. The vas deferens (*fig.*190, *f*) emerges from the upper or atlantal extremity of the testis (*e*); and, from its peculiarly extended, plicated, or folded course, seems to prolong the epididymis nearly to the neck of the bladder; the folds gradually diminish, and the duct itself enlarges, as it approaches its termination, which is in the beginning of the urogenital canal (*g*). This canal is continued through the pelvis and terminates in the vestibular passage, anterior to the orifice of the rectum (*q*).

The vascular tissue of the penis commences at the termination of the urogenital canal; it is separated by a median septum into two lateral moieties, and both are inclosed by a common dense fibrous sheath. The whole penis in its collapsed and retracted state is about fifteen lines in length, and is concealed in a large preputial sheath. The terminal half of the penis is formed by the glans, which presents a quadrilateral form, and is traversed by a median longitudinal furrow upon both the upper and the under surface. Its exterior is beset with numerous short and hard epidermal spines: its extremity is bifurcated, and each lobe is directed outwards and terminates in three or four spines, (*k*, *k*,) much larger, but softer, than the rest, and which are usually retracted in a depression.

A longitudinal azygos levator muscle runs along the upper surface of the penis; it arises by two lateral slips from the internal stratum (*n*) of the protrusive sphincter. Another longitudinal but longer and more slender muscle, the retractor penis, (*fig.* 190, *p*,) arises from the upper part of the base of the tail, bends downwards over the caudal muscles and vessels, and is inserted into the origin of the penis near the termination of the urogenital canal. The true urethra or canal of the penis begins by a small orifice at the root of the penis, near the termination of the urogenital passage, and by the combined action of the last described muscle with the sphincter cloacæ, it can be brought into closer approximation with the urogenital passage. It must be supposed that this temporary continuation of the urethra and urogenital passages takes place during the vigorous muscular and vascular actions of the parts in coitu, and that the semen is then propelled from the one along the other without escaping into the common vestibular compartment of the cloaca. Under ordinary circumstances, as when the urine is transmitted along the urogenital passage, it must escape into the vestibule, and may there be blended, as in the Bird, with the rectal excrement. The true seminal urethra, commencing by the distinct aperture, as above described, is about a line in diameter, and continues single to the middle of the glans, where it divides into two canals; each branch runs along the middle of the bifurcation of the glans, and, when arrived at the base of the large papillæ, subdivides into smaller channels corresponding with the number of the papillæ, and opening upon their apices. If the canal of the penis were slit open along its under part and thus converted into a groove, the male organs of the Ornithorhynchus would be then essentially like those of a Tortoise. The adhesion to the Mammalian type is manifested in a highly interesting manner by the completeness of the urethral canal, whilst the affinity to the Marsupial order is evinced in its bifurcation, corresponding with that of the glans itself. Had the penis been neither perforated nor grooved, as Cuvier once believed, the structure would have been extremely anomalous. That the existence of a penis is essentially and subordinately related to the sexual organs and not to the renal, is beautifully illustrated by the complete separation of the uro-urethral from the semino-urethral passages in the Monotremata.

The modifications by which the male organs in the Echidna differ from those of the Ornithorhynchus, are confined to the glans penis, which divides into four mammiloid processes, roughened by minute papillæ, and terminated by a depression in which is the branch of the seminal canal that traverses each process. Cowper's glands (*fig.*180, *k*, *k*, and *fig.*190, *h*) are of large relative size; they are situated between the base of the penis, the arch of the ischium, and internal part of the thigh: their secretion is carried by a long and slender duct (*fig.* 190, *m*) into the seminal urethra. The physiological relation of these glands to such a canal is clearly illustrated by their presence in the Monotremes, and their absence in the oviparous animals which have merely a seminal groove.

The *female organs of generation* (*fig.* 191) consist of two ovaria, the right much smaller than the left, two oviducts, two uteri, a clitoris, and mammary glands.

Female organs of generation, natural size, Ornithorhynchus. (Owen, Philos. Trans. 1832.*)*

The *ovaria* correspond in situation and surrounding attachments with the testes in the male; and the oviducts and uteri exhibit in their closely convoluted disposition an analogy with the long epididymis or vas deferens.

The left ovary (*fig.* 191, *f*) is an irregular, semi-elliptical, flattened body, with a wrinkled and slightly granulated surface in the unexcited state; but thicker, and with the surface studded by elevations formed by the ovisacs in different stages of development at the season of sexual excitement. At this period I have usually found two ovisacs, as in the figure, which are conspicuously larger than the rest, and presenting each a diameter of about two lines. The right ovary (*f′*) is a narrow, thin, generally elongated body; sometimes broader, with a finely granulated surface. It is often scarcely to be distinguished from the ovarian ligament to which it is attached. This ligament (*i*, *i*) arises from the posterior parietes of the abdomen, behind and a little on the outer side of the kidney, and passes along the edge of the broad ligament to the fallopian extremity of the oviduct, where it divides into two; one portion is attached to the side of the ovary, the other to the posterior margin of the fallopian orifice: after a course of an inch they again unite, and the ligament is continued along the anterior part of the uterus to its cervix, where it is insensibly lost. The two separated portions of the ligament support a large pouch of peritoneum which forms the ovarian capsule; the wide anterior orifice of the oviduct is also, by means of this ligament, prevented from being drawn away from the ovary.

The efferent tube of the ovarian products is present on both sides of the body, and is divisible into an oviduct, or fallopian tube, (*d′*,) and an uterus (*d*). The size of the latter is nearly equal on both sides, but the right oviduct is much shorter than the left, and corresponds with the abortive condition of the ovary. The external serous coat of the oviduct is loosely connected to the muscular coat by filamentary processes of cellular membrane, among which numerous tortuous vessels ramify. The muscular coat is thin and compact, and is most readily demonstrable in the uterus. The mucous coat is thin and smooth in the oviduct; it is thick, soft, plicated, but not villous, in the uterus.

The left *uterus* in a female with a large ovary, shot in the month of September, was two inches long, from four to five lines in diameter, and about a line thick in its parietes; it became suddenly contracted and thinner in its coats to form the oviduct, which presented a diameter of about two lines, slightly enlarging to within an inch of the extremity, which forms a wide membranous pouch, (*d″*,) opening into the capsule of the ovary by an oblong orifice or slit (*e*) of eight lines in extent. The edges of this orifice were entire, as in the oviducts of Reptiles, not indented as in the fimbriated extremity of the Fallopian tube in ordinary quadrupeds. The entire length of the oviduct and uterine tube, when detached from their connections with the mesometry, was nine inches. The right uterus and oviduct of the same specimen exhibited similar differences in diameter and structure, but was shorter, measuring only six inches in length.

In a specimen with a slightly developed ovary, killed by Mr. Bell in April, the uteri were not much wider than the oviducts, and not thicker in their coats; the entire tubes were much less in all their dimensions than those just described.

In the specimen above described with the large ovary, the thickened parietes of the first portion of the uterine tube depended chiefly on an increase of the inner membrane, which presents in a high degree the character of a secreting surface. This membrane at the cervix uteri presented in all the specimens many deep and close-set furrows, which, as the canal grew wider, were gradually lost, and the surface became more or less smooth in the different specimens, being most irregular in the specimen with the largest ovary. In the oviduct, the inner surface is at first smooth after leaving the uterus, but beyond that becomes finely reticulate, and in the terminal dilated part becomes again smooth. The cervix uteri makes a valvular projection analogous to an os tincæ on each side of the commencement of the uro-genital canal, just beyond the orifice of the urinary bladder. There are two orifices on each of these prominences; the lower one is the termination of the ureter, and a bristle is represented as passing through it in *fig.* 191; the upper or anterior orifice is the os uteri, *m*.

In young or virgin Ornithorhynchi this orifice forms scarcely any projection into the uro-genital canal, and it is divided by a narrow septum, or hymen.*

The *uro-genital canal* (*c*) is one inch and a half long, and three or four lines in diameter, but capable of being dilated to as great an extent probably as the pelvis will admit of; the diameter of the bony passage being seven-tenths of an inch. It is invested with a muscular coat, the external fibres of which are longitudinal, the internal circular. The inner membrane of this part is disposed in longitudinal rugæ more or less marked, but presents as little the character of a secreting membrane as that of the vestibule, being smooth and shining; the orifices of a few minute follicles are situated in the interstices of the rugæ near the orifice of the urinary bladder.

It is this division only of the passage from the uterus which is situated within the pelvis, the vestibule being produced beyond it, and the common outlet being in consequence situated at a considerable distance from the outlet of the pelvis.†

If the Ornithorhynchus were oviparous, its eggs must be disproportionately small compared with those of birds, in order to pass through the unyielding pelvis, unless the albumen and shell were subsequently added to the yolk in the

* Geoffroy, Mémoires du Museum, tom. xv. p. 32.

† In this structure, as well as in its aquatic life, the Ornithorhynchus resembles the Beaver.

vestibule. But, as has been before observed, neither the lining membrane of the vestibule nor that of the genito-urinary passage presents the characters of an active secreting membrane; and it is highly improbable that an almost callous surface daily traversed by the excrements, should be suddenly modified to contribute so important a share to the nutrient store of the embryo.

The common vestibule (*b*) is about one inch four lines in length, and varies from half an inch to an inch in diameter. The muscular fibres immediately investing it are disposed as follows. A thin circular muscle arises from a dorsal raphé which extends the whole length of the canal. Of this muscle the sacral fibres, or those nearest the outlet, surround the whole vestibule; but the atlantal or more internal fibres pass obliquely upwards, and surround the termination of the rectum only, serving as a sphincter to it. On the sternal aspect of the vestibule there are a series of longitudinal fibres, which extend from its external orifice to that of the urogenital cavity, the office of which is to approximate these orifices; and in this action the oblique fibres above described would assist, while at the same time they closed the rectum.

On the sternal aspect of the urogenital canal, and close to where it joins the vestibule, the clitoris is situated, which is consequently about an inch and a half distant from the external orifice of the vestibule. It is inclosed in a sheath upwards of an inch in length, and about two lines in diameter, of a white fibrous texture, and with a smooth internal surface, and this sheath communicates with the vestibule about a line from the external aperture. The clitoris itself is a little flattened body shaped like a heart on playing cards; it is about three lines long, and two lines in diameter at its dilated extremity, where the mesial notch indicates its correspondence of form with the bifurcated penis of the male. From the shortness of the clitoris, and the length of its sheath, it is obvious that no part of it can project into the vestibule in the ordinary state of the parts, as stated by Sir Everard Home, its extremity being situated at least an inch distant from where its sheath communicates with that cavity.

At the base of the clitoris are two small round flattened glands, the analogues of Cowper's glands in the male, which open into the sheath or preputium clitoridis. These glands were largest in the specimen whose uterine organs were most developed.

The vestibule is lined by a dark-coloured cuticular membrane, and has a tolerably uniform surface. The rectum opens freely into it posteriorly, as indicated by the probe *b'*, in *fig.* 191; the line of distinction in the relaxed state of the sphincter above-mentioned being little more than a change in the character of the lining membrane.

The urogenital canal, on the contrary, opens into the vestibule by a contracted orifice, and, in one of the specimens examined, made a small circular and valvular projection into that cavity.

On either side the termination of the rectum there are from six to eight small apertures of dark-coloured glands or follicles, about the size of a pin's head, situated immediately behind the proper membrane of the vestibule, and corresponding with the anal follicles of the Marsupial and other Quadrupeds.

The female organs of the Echidna correspond in all essential points with those of the Ornithorhynchus.

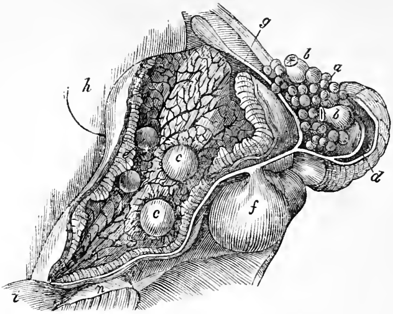
Products of generation.—The mode of generation and course of development of the Monotremata, although elucidated in many essential points by the light of anatomy and analogy, still demand observation of the breeding animals, and of the impregnated uterus and embryo in several stages, before they can be fully determined.

The close resemblance of the efferent tubes, in their complete separation and in their mode of termination, with the oviducts of Reptiles, and more especially of the Oviparous tortoises, added to the approach to the very peculiar condition of the female organs in Birds which the Monotremes offer in the unequal development of the ovaria and oviducts, have inclined several physiologists to a belief in the reports which from time to time have been published of the discovery of eggs in the nests of the Ornithorhynchus. But a comparison of the organs themselves with the conditions essential to the Oviparous generation of a warm-blooded animal offers almost insuperable difficulties to this view. The difference of structure and dimensions between the uterine and oviducal divisions of the efferent canal is greater in the Ornithorhynchus than in any bird, and so closely corresponds with that which characterizes the uterus and oviduct in the Kangaroo, that it is highly probable they perform similar functions in the completion and development of the ovum.

But the experienced physiologist would seek to obtain a closer insight into the mode of generation of the Monotremes by a comparison of the more essential generative organ,—the ovary,—with that of the bird. Now it has been shown that this organ, at the period of sexual excitement, does not differ in size or form from that of the Rodent or Marsupial quadruped; nay, that some of the latter tribe, as the Wombat, more nearly resemble the bird in the large size of the ovisacs or calyxes than the Monotremes are known to do. A yolk of large size appears, however, to be an essential condition of an egg which is to be hatched by a warm-blooded animal out of the body; but the vitelline portion of the ripe or nearly ripe ovarian ovum of the Ornithorhynchus does not equal the twentieth part of the yolk of the egg of a bird of corresponding size: and it is scarcely necessary to observe that the yolk is always exclusively a product of the ovarium, and that the material added to it by the oviduct or uterus must be analogous to the albumen, chalazæ, and cortical investments of the bird's egg.

The unimpregnated ovarian ovum from an ovisac of two lines in diameter, of the Ornithorhynchus, is of a spherical form, and very nearly fills the ovisac. The diameter of the germinal vesicle is to that of the ovum as 1 to 38. The vitelline fluid is rich in the number of its nucleated cells or granules, and the intermixed, clear, colourless oil-globules. The vitelline membrane is moderately thick, smooth, and highly refracting. The ovum is separated from the ovarian vesicle, or lining membrane of the ovisac, by a very small quantity of fluid and a stratum of granules or cells. The proper tunic of the ovisac consists of a dense and very vascular layer of the 'stroma' or proper tissue of the ovary, which is rather thicker and more distinctly laminated than in most Mammalia, and in this respect widely differs from the lax stroma of the ovary of the bird. The most important difference to be noted in the present comparison with the bird is the small size of the ovarian ovum, depending on the relatively scanty amount of vitelline matter, superadded in the ovary to the essential part of the ovum, the vesicula germinativa.

Fig. 192.



Left uterus impregnated, Ornithorhynchus. (*Owen, Phil. Trans.* 1834.)

It may be objected that the impregnated ovarian ova in birds rapidly augment in bulk as the time of dehiscence approaches, and that, although the ovaria of the Ornithorhynchus may have been investigated within a few days of the reception of the impregnated ovum into the oviduct, the changes occurring in such a period might much more nearly approximate the ovarian ovum of the Ornithorhynchus to the size and other conditions of that of the bird than in the instances above described.

The following observations on the impregnated ovum in the uterus itself prove, however, that no such approximation to the bird in regard to the proportion of yolk added to the ovarian ovum, or as respects the size of the ovum prior to dehiscence, is made by the Ornithorhynchus.

For the acquisition of this important evidence in the question of the generation of the Monotremata science is indebted to the exertions of Mr. Geo. Bennett, F.L.S., a Member of the Royal College of Surgeons in London, and Colonial Zoologist at Sydney, New South Wales. Three uteri, containing undeveloped ova, were transmitted by that gentleman to the Museum of the Royal College of Surgeons, in 1834, and with the sanction of the Board of Curators, were described by me in the Philosophical Transactions of that year.*

In these specimens the left ovary only had taken on the sexual actions, but did not exceed in size the same parts in the unimpregnated specimens above described. The right ovary had, however, become enlarged; it measured half an inch in length, a third of an inch in breadth, and was about half a line in thickness: a few ovisacs, about the size of a small pin's head, projected from the surface. The left ovary in each of the specimens was concealed by the thin membrane forming the expanded orifice of the oviduct, to which it was agglutinated by a coagulated secretion. In two of the specimens the left ovary presented two empty ovisacs, or corpora lutea (*fig.* 192, *b b*), corresponding with the number of ova found in the uterus. In the third specimen the left ovary presented two ovisacs still uncicatrized; but only one ovum was contained in the uterus. In a fourth specimen three similar ovisacs were present, but the ova had been removed from the uterine cavity. The discharged ovisacs were of an elongated flask-shaped form about three lines in length, and two in diameter, with the margins of the orifice, through which the ovum and granular substance had passed, everted, with a slight contraction, resembling the neck of a flask, below the aperture. On compressing these ovisacs, small portions of coagulated substance escaped. When longitudinally divided, they were found to consist of the same parts as the ovisac before impregnation, with the exception of the granular contents and granular stratum; but the theca, or innermost parietes of the sac, was much thickened, and encroached irregularly upon the empty space, so as to leave only a cylindrical passage to the external opening.

The impregnated Ornithorhynchus, in the uterus of which the two smallest sized ova were found, was shot on the evening of the 6th of October, 1832, in the Yas river, Murray County, New South Wales. These ova were of a semitransparent white colour when recent, but had lost that appearance when examined at the Museum, to which they had been transmitted, *in situ*, with the uterus and surrounding parts well preserved in spirits. The ova were situated at the upper part of the left uterus, and at the distance of about a line from each other. Each ovum was spherical in form, and measured two lines and a half in diameter; they were of a deep yellow colour,

* See vol. cxxiv. p. 555, and Physiol. Catalogue of the Hunterian Museum, vol. v. p. 112, No. 3460 A.

with a smooth and polished surface, and had not the slightest adherence to the uterine parietes.

The specimen containing the two ova next in size (*fig.* 192, *c c*) was shot in the same locality on the 7th of October. These ova measured each three lines in diameter, and were situated a little below the middle of the left uterus: they were of a spherical form, but had evidently been slightly compressed in the uterine cavity. They were of a lighter colour than the preceding; a circumstance which was specially evident at the upper part, from the subsidence of the contained vitelline mass. Externally they were smooth and rolled freely out of the position where they were lodged, like those of the preceding specimen.

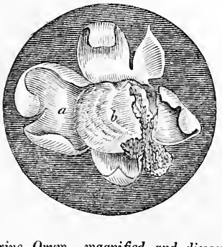
The third specimen, in the uterus of which the largest ovum was contained, was shot on the evening on which the first specimen was obtained. This ovum had the same spherical form, smooth exterior surface, and freedom from connexion with the uterus, as in the preceding; but was of a much lighter colour, owing to the increased quantity of its fluid contents, to which its greater size was chiefly attributable. It measured three lines and a half in diameter, and had been situated in a depression or cell a little below the middle of the left uterus. The lining membrane of the uterus was highly vascular in the recent state in each of the above specimens.

In all these ova the contents could be seen, through the cortical or outer membrane, to be of two kinds, viz. a greyish sub-transparent fluid, and a yellowish denser mass, which varied in their relative proportions as above-mentioned, the denser substance always subsiding to the lowest part of the ovum, whichever way it was turned.

In the largest ovum, the yellow mass or yolk occupied about one-third of its cavity, while in the smallest it constituted four-fifths of the whole mass.

The chorion or cortical membrane of these ova (*fig.* 193, *a*) offered a moderate degree of resistance when torn open with the forceps, and yielded equally in every direction when separated from the yolk, the rent margins curling inwards like the coat of an hydatid. This membrane is of a dull greyish colour, inclining to brown, slightly transparent, and more polished upon its inner than upon its outer surface: it resembles the cortical membrane of the ovum of the Salamander, but is of a more delicate texture. The fluid contents occupied the space between the cortical and vitelline membranes, a situation analogous to that of the albumen in the egg of the fowl, but had not become coagulated by the action of the spirit in which it had been so long immersed.

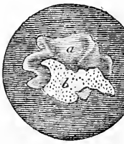
Fig. 193.



Uterine Ovum, magnified and dissected, Ornithorhynchus.
(Owen, Phil. Trans. 1834.*)*

The yellow matter, or yolk, was seen to be invested by its proper capsule (*fig.* 193, *b*), which, when reflected under the microscope, was found to consist of an extremely thin, smooth, and transparent outer layer, which I regard as the membrana vitelli (*fig.* 194, *a*), with a thicker granular membrane immediately lining it, analogous to the *blastoderma* or germinative stratum (*fig.* 194, *b*).

Fig. 194.



Portion of the vitelline membrane and germinal stratum, Ornithorhynchus.
*(Owen, Phil. Trans.*1384.*)*

The contents of the above investments, or substance of the yolk, consisted of innumerable minute opaque granules, similar in size and regularity of form to those contained in the ovarian follicles; and with these granules were mingled larger transparent globules of oil. There was not the slightest trace of chalazæ attached to the vitelline membrane, as from analogy we might have expected, had the ovum been destined to have been perfected by incubation. I was unable to detect any rudiments of the embryo: an opaque streak was discernible on one part of the yolk, but not sufficiently definite to be satisfactorily recognised as a cicatricula; it is indeed, probable, from the observation of Lieutenant Maule,* that the ova attain a greater size by the imbibition of the nutrient material before the lineaments of the fœtus become visible.

The changes which the impregnated uteri of the Ornithorhynchus had undergone, as compared with the same part in the quiescent state, were greater than those which have been observed to take place in the Kangaroo. The uterus containing the two smallest sized ova measured seven lines in diameter, but was much firmer and denser than in the unimpregnated specimens; and having also increased in length, was thrown into more abrupt curves on either side of the ovarian ligament. The uterus which had contained the largest ovum measured an inch in diameter; and that containing those of the second size was of

* Proceedings of the Zoological Society, 1832. "In the insides of several female platypi which were shot, eggs were found of the size of a large musket-ball and downwards."

nearly the same size (*fig.* 192). The right uterus in all the specimens had become sympathetically affected, being firmer in texture and thicker in its coats.

The parietes of the impregnated uteri were from three to four lines in thickness; an increase which was principally occasioned by the extension of small vascular folds between the fibrous and internal coats, which were so placed at right angles to these tunics as to present an appearance very similar to that of the second cavity of the stomach of the Porpesse. The fibrous coat was slightly thickened near the cervix, and the serous covering was separated from it by the ramifications of numerous large and tortuous uterine vessels.

There was not the slightest trace of a decidual or adventitious membrane in the cavity of the womb; and especial attention was directed to this circumstance, in consequence of the office assigned to it in a recent work,* as ministering support to the ova in the higher *Mammalia*, at a period when, like those of the Ornithorhynchus, they have no attachment to the uterine parietes.†

It may, however, be said that the deciduous membrane is here represented by the cortical or outer covering of the ovum: but this membrane, though of a denser structure and without villi, is certainly analogous to the outer tunic of the uterine ovum of the Rabbit and Bitch, which in them is gradually separated from the vitelline membrane by the imbibition of albuminous fluid. Now the relative proportion of the fluid interposed between the cortical and vitelline membranes in the small and large ova of the Ornithorhynchus, shows that the mutual recedence of the two membranes is effected in the same way.

If the form, the structure, and the detached condition of the ova of the Ornithorhynchus, should still be regarded by some as compatible with, and perhaps favourable to, the opinion that they are excluded as such, and that the embryo is developed out of the parent's body, the following objections oppose themselves to such an opinion: the only part of the efferent tube of the generative apparatus which can be compared in structure or relative position to the shell-secreting uterus of the Fowl, is the dilated terminal cavity in which, in all the specimens above described, the ova were situated; and upon the oviparous theory it must be supposed either that the parietes of this cavity, after having secreted the requisite quantity of soft material, suddenly assume a new function and complete the ovum by providing it with the calcareous covering necessary to enable it to sustain the superincumbent weight of the mother during incubation; or, that this is effected by a rapid deposition of the same material from the cuticular surface of the external passages; or lastly, according to a more recent, but still more improbable supposition, by a calcareous secretion of the abdominal glands poured out upon the ovum after its exclusion.*

But granting that the egg is provided in any of these ways with the necessary external covering, yet from the evidence afforded by the specimens under consideration, the ovum is still deficient in those parts of its organization which appear to be essential to successful incubation, viz. a voluminous yolk to support the germinal membrane, and the mechanism for bringing the cicatricula into contiguity with the body of the parent. Add to this, that such a mode of development of the fœtus requires that all the necessary nutritive material be accumulated in the ovum prior to its exclusion. Now the bony pelvis of the bird is expressly modified to allow of the escape of an egg, both large from the quantity of its contents, and unyielding from its necessary defensive covering; but whatever affinities of structure may exist in other parts of the Ornithorhynchus, it is most important to the question of its generation to bear in mind that it manifests no resemblance to the bird in the condition of the pubic bones.

Again, as we have seen that the ova of the Ornithorhynchus have attained a diameter of little more than two lines after having traversed the whole of the Fallopian tube, the length of which is six inches, and the internal secreting surface increased by numerous folds, it may be reasonably inferred, from the analogy of the Rabbit and other Mammalia, that the ovum was of much smaller dimensions when first received into the oviduct. But the yolk in Birds and Oviparous Reptiles is invariably the product of the ovary, and derives no appreciable increase from the secretions of the efferent tube, which supply only the albuminous part of the egg, or the material for the first formation of the chick. If, therefore, the gestation of the Ornithorhynchus terminates by the exclusion of an egg, as in the Bird or Tortoise, the preparatory steps in the formation of the ovum are widely different, for the parts concerned manifest the essential characters of the Mammiferous type, and the germ itself has a corresponding structure.

These facts, it is agreeable to find, are in exact accordance with the now ascertained functions of the abdominal glands; for since the yolk in the Bird, besides its uses in the course of the fœtal development, is intended as an after-substitute for a mammary secretion, remaining, as it does, but little diminished at the close of incubation, it might have been concluded, from *à priori* physiological deduction, that the Monotremes, in which no such substitute is required, would approximate the other Mammalia in the small size of the ovarian ovum.

The nature or amount of subsequent deviations from a true viviparous generation can be determined only by future examinations of more advanced ova. From the structure of the cor-

* *Breschet*, Etudes de l'Œuf Humain.

† In the recent specimens *Mr. Bennett* noticed besides the ova only a "moisture" in the uterus.

* Geoffroy St. Hilaire, Gazette Medicale, Feb. 11, 1833.

tical membrane it is probable that this does not become organized into a placenta, and that the *Monotremata* like the *Marsupiata* are essentially ovoviviparous. Since, however, the female Ornithorhynchus has no tegumentary pouch to protect a prematurely born offspring, it must be presumed that the fœtus acquires greater proportional bulk* and more mature strength by a longer continuance within the uterus. In this case it may be doubted whether the vitelline vesicle will suffice for nourishment and respiration through the whole period of development, and the allantois and umbilical vessels will probably be more expanded for that purpose.

The means of prosecuting this inquiry are the more likely to be afforded, since, through the exertions of Mr. Bennett, the period when the pregnant female may be procured is now ascertained. Had not a specimen, supposed to be in this condition, which my friend had obtained alive, unfortunately escaped from its confinement, he would, there is little doubt, have ascertained the true nature of the generative product, and the probable duration of gestation.

With reference to the latter point, Mr. Bennett observes, that two months after the capture of the female specimen with the smallest ova, viz. on the 8th of December, 1832, he succeeded in laying open one of the burrows of the Ornithorhynchi on the banks of the Murrumbidgee River, in which three living young ones were found: they were naked, and measured only one inch and seven-eighths in length, and he considers them to have been recently brought forth. Not having any means of preserving these specimens, and being at a great distance from Sydney, they were lost. The nest was most carefully scrutinized by Mr. Bennett, but not the slightest trace of an egg-shell could be perceived in it.

The principal points, therefore, in the generative economy of this paradoxical species which still remain to be determined by actual observation are—

1st. The manner of copulation.

2d. The season of copulation. (This is probably at the latter end of the month of September or beginning of October.)

3d. The period of gestation. (This is probably six weeks.)

4th. The nature and succession of the temporary structures developed for the support of the fœtus during gestation.

5th. The exact size, condition, and powers of the young at the time of birth.

6th. The act of suckling.

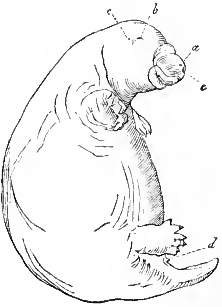
7th. The period during which the young requires the lacteal nourishment.

8th. The age at which the animal attains its full size.

I have ascertained the following particulars respecting the young Ornithorhynchus, probably not long excluded from the fœtal envelopes, by an examination of two specimens, obtained by Lieut. the Hon. Lauderdale Maule, from two different nests, discovered by him in the banks of the Fish River, Australia, and presented by Dr. Weatherhead to the Zoological Society of London.

Subjoined is an outline of the smaller of these specimens of the natural size (*fig.* 195).

Fig. 195.



Young Ornithorhynchus. (Original.)

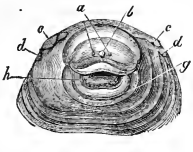
The following are admeasurements of these two specimens:—

	Smaller Ornithorhynchus. In.	L.	Larger Ornithorhynchus. In.	L.
Length from the end of the upper jaw over the curve of the back to the end of the tail	3	9	6	6
Length from the same points in a straight line along the abdomen..............	2	1	4	0
Greatest circumference of the body	2	9	4	8
Length of the head	0	8½	1	0
Length of the upper mandible	0	3	0	5
Breadth of the upper mandible at the base	0	4	0	6
Thickness of the upper mandible at the anterior margin	0	0⅔	0	1
Length of the lower mandible	0	2	0	2½
Breadth of the lower mandible at the base........	0	3	0	5
Length of the tail from the vent	0	4½	0	10
Breadth of the tail at the root	0	4	0	8
Length of the fore foot	0	3	0	5
Breadth of the fore foot....	0	3½	0	5
Length of the hind foot....	0	4	0	8½
Breadth of the hind foot ..	0	3	0	5
Distance between the eyes..	0	3⅔	0	6
Distance between the nostrils	0	1½	0	1½
From the exterior nostrils to the end of the mandible	0	1½	0	2
From the tip of the tongue to the end of the lower mandible	0	0¼	0	0½

* In reference to this point it may be observed, that the kidneys are not lodged low down in the pelvis as in the true *Ovipara*, but occupy the position characteristic of the Mammiferous type of structure, which allows free space for the enlargement of the uterus during pregnancy.

The circumstances which first attract attention in these singular objects are the total absence of hair,* the soft flexible condition of the mandibles, and the shortness of these parts in proportion to their breadth as compared with those of the adult.

Fig. 196.



Head of young Ornithorhynchus. (Owen, Zool. Trans.)

The integument with which the mandibles are covered is thinner than that which covers the rest of the body, and smoother, presenting under the lens a minutely granulated surface when the cuticle is removed, which, however, is extremely thin, and has none of the horny character which the claws at this period present. The margins of the upper beak are rounded, smooth, thick, and fleshy; the whole of the under mandible (*fig.* 196, *g*) is flexible, and bends down upon the neck when the mouth is attempted to be opened. The tongue, (*fig.* 196, *h*,) which in the adult is lodged far back in the mouth, advances in the young animal close to the end of the lower mandible; all the increase of the jaws beyond the tip of the tongue, which in the adult gives rise to a form of the mouth so ill calculated for suction or application to a flattened surface, is peculiar to that period, and consequently forms no argument against the fitness of the animal to receive the mammary secretion at an earlier stage of existence. The breadth of the tongue in the larger of the young specimens was 3½ lines; in the adult it is only one line broader; and this disproportionate development is plainly indicative of the importance of the organ to the young animal, both in receiving and swallowing its food. The mandibles are surrounded at their base by a thin fold of integument, which extends the angle of the mouth from the base of the lower jaw to equal the breadth of the base of the upper one, and must increase the facility for receiving the milk ejected from the mammary areola of the mother. The oblique lines which characterize the sides of the lower mandible in the adult were faintly visible on the corresponding parts of the same jaw of the young animal: a minute ridge of the inner sides of these lines indicates the situations of the anterior horny teeth of the adult.

The situation of the exterior nostrils (*figs.* 195, 196, *a*) has already been given; they communicate with the mouth by the *foramina incisiva*, which are situated at nearly three lines distance from the end of the upper mandible, and are each guarded by a membranous fold extending from their anterior margin: the nasal cavity then extends backwards, and terminates immediately above the larynx, the tip of the epiglottis extending into it, and resting upon the soft palate.

On the middle line of the upper mandible and a little anterior to the nostrils there is a minute fleshy eminence lodged in a slight depression (*fig.*196, *b*). In the smaller specimen this is surrounded by a discontinuous margin of the epidermis, with which substance, therefore, and probably (from the circumstance of its being shed) thickened or horny, the caruncle had been covered. It is a structure of which the upper mandible of the adult presents no trace, and is obviously analogous to the horny knob which is observed on the upper mandible in the fœtus of aquatic and gallinaceous Birds. I do not, however, conceive that this structure is necessarily indicative of the mandible's having been applied, under the same circumstances, to overcome a resistance of precisely the same kind as that for which it is designed in the young Birds which possess it. The shell-breaking knob is found in only a part of the class; and although the similar caruncle in the Ornithorhynchus affords a curious additional affinity to the *Aves altrices*, yet, as all the known history of the ovum points strongly to its ovo-viviparous development, the balance of evidence is still in favour of the young being brought forth alive.

The situation of the eyes (*fig.*195, *b*, 196, *c*) was indicated by the convergence of a few wrinkles to one point; but when, even in the larger of the two specimens, these were put upon the stretch, the integument was found entire, and completely shrouding or covering the eyeball anteriorly. This fact is one of great importance to the question of the mammiferous character of the Ornithorhynchus. For on the supposition of the young animal possessing locomotive faculties, which would enable it like the young gosling, immediately after birth or exclusion, to follow the parent in the water, and there to receive its nutriment, (whether mucous or otherwise,*) the sense of vision ought certainly

* This is not accidental, as in many of the adult specimens sent over in spirit, for the cuticle is entire. In the specimens which Mr. G. Bennett discovered, the skin had a slight downy appearance.

* Geoffroy St. Hilaire contending, in 1833, for the analogy of the abdominal glands of the Ornithorhynchus with those of the Shrews which secrete "a *mucus* possessing a very powerful odour," says, "I should not be surprised, if this mucus, more abundant and more substantial in the Monotremata, became the nutriment of the young after their hatching. The Monotremata would act, in this respect, like some aquatic birds which conduct their young after hatching to the water, and assist them in their sustentation. The maternal instinct would lead the female Ornithorhynchus to effect the contraction of the gland, which is possible by the efforts of the panniculus carnosus and the great oblique muscle, between the fibres of which the gland is seated, and thus procure for the young, at several periods of the day, by way of nutriment, an abundant supply of mucus. If this education is carried on in the water, where we know, by the history of the generation of frogs and the nutrition of their tadpoles, that the mucus combines with the ambient medium, becomes thick, and supplies an excellent nutriment for the early age of these reptiles, we shall understand the utility of the ventral glands of the Ornithorhynchus, as furnishing a source of nutriment for the young of these animals,—for young *Ovipara* newly hatched."—*Gazette Médicale*, Feb. 18th, 1833.—*Proceedings Zool. Society*, March 1833, p. 29.

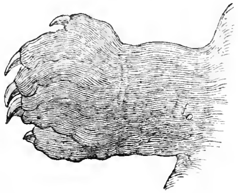
to be granted to it in order to direct its movements. The privation of this sense, on the contrary, implies a confinement to the nest, and a reception on land of the mammary secretion of the parent.

The auditory orifices (*fig.* 196, *d*) are situated about a line behind the eyes.

The general form of the body and the cartilaginous condition of the bones of the extremities equally militate against the young Ornithorhynchus possessing, at this period of its existence, active powers of swimming or creeping. The head and tail are closely approximated on the ventral aspect, requiring force to pull the body out into a straight line; and the relative quantity of integument on the back and belly shows that the position necessary for the due progressive motions is unnatural at this stage of growth.

The toes on each of the four feet were completely formed, and terminated by curved, conical, horny claws; but the natatory fold of membrane of the fore foot had not the same proportional extent as in the adult, and the spur of the hind foot did not project beyond its socket in either specimen. In the smaller one, which was a male, it presented the form of an obtuse papilla; while in the larger specimen, although a female, it was more plainly developed and more pointed (*fig.* 197, *f*). This circumstance is in exact accordance with the known laws of the development of sexual distinctions, especially of those of secondary importance, such as beards, manes, plumes, horns, tusks, spurs, &c., which do not avail in distinguishing the sexes till towards the period of puberty. As the spur is the only obvious distinction of the sexes in the full-grown Ornithorhynchus, I was compelled to refer to the internal essential organs, in order to determine the sex of the specimens here described.

Fig. 197.



Hind-foot and spur, young female Ornithorhynchus, magnified. (Owen, Zool. Trans.)

The ventral surface of the smaller specimen was carefully examined with a lens; but no trace of an umbilicus could be satisfactorily determined. In the very young or newly born Kangaroo, a longitudinal linear trace of the attachment of the umbilical vesicle is at that time apparent, but it is rapidly obliterated; as is probably also the case in the Ornithorhynchus.

In the smaller specimen the intromittent organ projected a little way beyond the excrementory orifice, as in the young Marsupialia; but it was not continuous, as in them, with the anterior margin of that outlet. In the larger female specimen the corresponding organ was visible just within the verge of the opening; but this clitoris, remaining stationary in its development, is afterwards, as I have shown in my paper on the Mammary Glands of the Monotremes,* removed to a distance from the preputial aperture by the elongation of the sheath, just as the minute spur of the female lies concealed at the bottom of the progressively elongated tegumentary socket, and as the tongue is left at the back of the oral cavity by the growth of the jaws.

The following anatomical appearances were noticed in these young Ornithorhynchi:—

On laying open the abdomen in the larger specimen, the most prominent viscus was the stomach, which was almost as large as in the adult animal, deriving at this period no assistance from the preparatory digestive cavities, the cheek-pouches, which were not yet developed. The stomach extended in a curved direction across the epigastric and down the left hypochondriac region to the left iliac region. It was full of coagulated milk.

In the smaller specimen the stomach was empty; when distended with air it exhibited a less disproportionate development. It was situated in the left hypochondriac and lumbar regions. The intestines contained air, with granular masses of a mucous chyme adhering to their internal surface. This condition of the digestive canal would seem to show that no long period had elapsed since the birth of the specimen, and that either lactation had not been in full action, or that the young one had been deserted by the parent for some time before it was taken.

In both specimens the spleen bore a proportionate size with the stomach; and as the difference in the development of the stomach was considerable, the correspondence between the condition of the spleen with that of the digestive cavity was made very obvious.

The difference in the development of the liver was not greater than corresponded with the different size and age of the two specimens. But the pancreas in both bore the same ratio to the stomach as the spleen. This, therefore, would seem to afford some indication of the organs with which the function of the spleen is more immediately related.

The intestinal canal in the larger specimen was situated almost entirely on the right side of the *abdomen*. The *cæcum* in both was very minute and filamentary. I examined the *ileum*, and more especially in the usual situation above the *cæcum*, but could not perceive any trace of the pedicle of the umbilical or vitelline vesicle. The other vestiges of fœtal organization were more obvious than in the ordinary marsupial or ovoviviparous Mammalia.

In both specimens, but more especially in the smaller one, the umbilical vein was seen, extending from a linear cicatrix of the perito-

* Phil. Trans. for 1832, p. 525.

neum, opposite the middle of the abdomen, along the anterior margin of the suspensory ligament to the liver. It was reduced to a mere filamentary tube, filled with coagulum. From the same cicatrix the remains of the umbilical arteries extending downwards, and near the urinary bladder, were contained within a duplicature of peritoneum, having between them a small flattened oval vesicle, the remains of an allantois, which was attached by a contracted pedicle to the fundus of the bladder.

As both the embryo of the Bird and that of the ovoviviparous Reptile have an allantois and umbilical vessels developed, no certain inference can be drawn from the above appearances as to the oviparous or viviparous nature of the generation of the Ornithorhynchus. But the structure of the ovary and that of the ovum, both before and after it has quitted the ovisac, afford the strongest analogical proof of the intra-uterine developement of the embryo, and at the same time accord with the ascertained fact of the mammary nourishment of the young animal.

The kidneys were situated remote from the *pelvis* and high up in the lumbar region.

The situation of the kidneys with respect to each other varied in the two specimens; in the larger one, the left was a little higher than the right; in the smaller one it was a little lower; the latter is the ordinary position in the adult. The supra-renal glands did not correspond with this arrangement, but in both instances the right was higher than the left, agreeing with the relative position of the testes in the male, and the ovaries in the female. In Man the large size of the supra-renal glands is noted as a fœtal peculiarity, but in the Ornithorhynchus they are of minute size, their greatest diameter not exceeding one-eighth of a line in the smaller specimen here described; and they increase in size progressively with the growth of the animal, and in a greater proportion than the kidneys, which increase would appear, therefore, to have relation to the development of the generative organs. There were no traces of the *corpora Wolffiana*.

The *testes* in the small male specimen were situated a little below the kidneys: they were of an elongated form, pointed at both ends, with the epididymis folded down, as it were, upon their anterior surface. In the female, the ovaries were freely suspended to the loins in a similar position, the right being at this period as large as the left: it is the persistence of the latter at an early stage of development which occasions the disproportionate size of the two glands in the adult. The still greater inequality of size in the oviducts of the Bird arises, as is well known, from a similar arrest of the development of the one on the right side, but both are equal at an early stage of existence. The uteri were straight linear tubes, scarcely exceeding the size of the ovarian ligaments.

The lungs were found amply developed in both specimens; the air-cells remarkably obvious, so as to give a reticulate appearance to the surface, and a resemblance to the lungs of a turtle. They had evidently been permeated by air in the smaller specimen.

The heart, in both specimens, was of the adult form, with the apex entire; but the left auricle was proportionately larger than in the adult heart.

The *ductus arteriosus* was here very evident, and formed a filamentary chord in the usual situation between the aorta and pulmonary artery, but proportionately longer than in the true viviparous Mammalia. Here also we have the indication of a more prolonged fœtal existence than in the marsupial animals, there being no trace of a ductus arteriosus either in the uterine or mammary fœtus of the Kangaroo.

The Ornithorhynchus also deviates from the ordinary Marsupialia in having the *thymus* gland. This is situated in front of the great vessels of the heart, and consists of two lobes, of which the right is the largest. The traces of fœtal structures presented by these young Ornithorhynchi, and especially the allantoic dilatation of the urachus, indicate that the Monotremata differ from the Marsupialia in a longer continuance of the true fœtal or intra-uterine existence.

Mammary organs.—In this section will be adduced the evidence in proof of the essentially Mammalian nature of the Monotremes which the presence and ascertained function of the mammary glands have yielded.

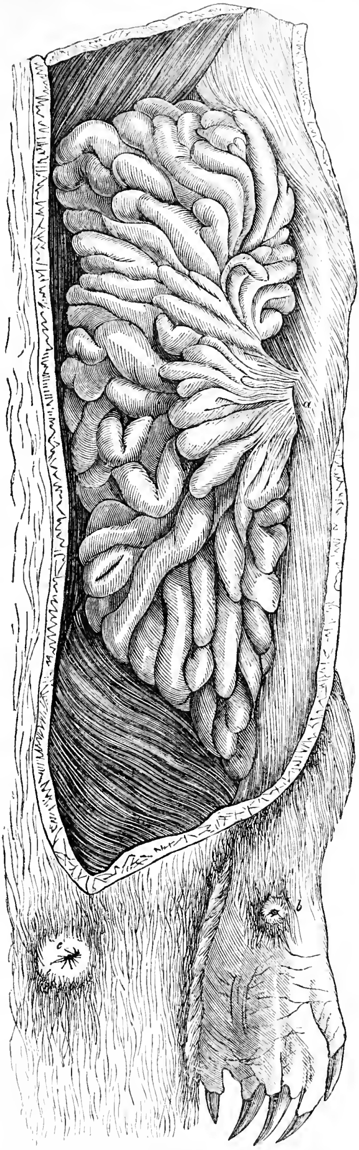
The most important result of Professor Meckel's anatomical investigations of the *Ornithorhynchus* was his discovery of the two large abdominal subcutaneous glands: these he concluded to be the mammary organs, which until that period had been supposed to be absent in the Ornithorhynchus.

Subjoined is the figure which Meckel has given of one of these glands in its natural relative position, *fig.* 198. It measured four inches and a half in length, two inches in breadth, and half an inch in thickness.

From this apparently conclusive evidence of the affinity of the Ornithorhynchus to the Mammalia, Professor Meckel, however, is far from drawing conclusions as to the identity of their mode of generation. For assuming that the difference between the bringing forth of living young and of eggs is really very small and by no means of an essential nature, and remarking that birds have accidentally hatched the egg within the abdomen and so produced a living fœtus,—an occurrence which has also been induced by direct experiment, and that, lastly, the generation of the Marsupial animals is very similar to the oviparous mode, he deems it very probable that as the Ornithorhynchus approaches still nearer than the Marsupial animals to Birds and Reptiles, its mode of generation may be in a proportionate degree analogous. For an animal possessing mammary glands he claims, however, the right to rank with the Mammalia, agreeing with Professor Geoffroy only so far as to consider the Monotremata as a distinct order of quadrupeds, which he places, as Cuvier has done, next to the Edentata.

Against this conclusion, however, Professor

Fig. 198.

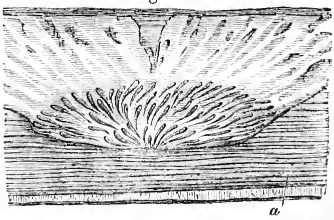


Mammary gland, Ornithorhynchus, nearly arrived at full size. (Meckel.)

Geoffroy has argued (Annales des Sciences Nat. ix. 1826, p. 457) that the subcutaneous abdominal glands considered by Meckel as mammary, possess none of the characters of a true mammary gland; he states that he examined them with the greatest attention, comparing them with the human mammary glands, and especially with those of Marsupial animals, and that they were of a totally different texture, consisting of a vast number of *cæcums* placed side by side, all directed to the same point of the skin, where *only two* excretory orifices were to be perceived, and these orifices so small that the head of the smallest pin could not be made to enter them. That above all there was no trace of nipples; that in the specimen examined by him, which had the size and appearance of an adult female, the apparatus in question was not more than a fourth part the size of that observed by Meckel. But a mammary gland, Professor Geoffroy observes, when arrived at its full development, occasions an enlargement of all its constituent parts, the nipple acquiring additional bulk even before lactation commences, and that there was no appearance of this kind in the Ornithorhynchus. He considers, therefore, these abdominal glands as analogous to those which are situated along the flanks of Salamanders, and still more to the odoriferous glandular apparatus which is concentrated at the sides of the abdomen in the Shrews.

In the absence of direct testimony of the nature of the secretion of the abdominal subcutaneous glands of the female Ornithorhynchus, the next obvious step was to test their disputed nature and office by an examination of their periods of increase and functional activity, as compared with those of the ovaria. If these glands had been analogous to the scent-glands of the flanks in the Shrews, and if their secretion had been destined to attract the male to the sexual intercourse, as suggested by Professor Geoffroy, their development ought to have proceeded *pari passu* with that of the ovaria, and the enlargement of both organs ought to have simultaneously reached its maximum. But in specimens in which the ovisacs were enlarged so as to indicate the ova to be ripe for development, I found* that the abdominal glands had made a comparatively slight progress to their full size (*fig.* 199). This

Fig 199.



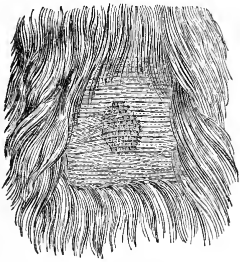
Mammary gland, Ornithorhynchus, natural size at non-breeding season.
(Owen, Phil. Trans. 1832.)

* Philos. Trans. 1832, p. 525.

condition was only manifested in the females with ovaria, large indeed, but without prominent ovisacs, and in which the recent corpora lutea were almost absorbed. These facts were established by the dissection of five female Ornithorhynchi.

In each of these specimens the mammary gland was composed of between one hundred and two hundred elongated subcylindrical lobes, forming an oblong flattened mass, and converging to a small oval areola in the abdominal integument, which areola is situated between three and four inches from the cloaca, and about one inch from the mesial line. The lobes in the fully developed glands are rounded and enlarged at their free extremities, and measured at that end three or four lines in breadth, and became narrower to about one-third from the point of insertion, where they end in slender ducts. Almost all the lobes are situated at the outer side of the areola, and consequently converge towards the mesial line of the abdomen. Between the gland and the integument the panniculus carnosus (*fig.* 199, *a*) is interposed, closely adhering to the latter, but connected with the gland by loose cellular membrane. This muscle is here a line in thickness, its fibres are longitudinal, and, separating, leave an elliptical space for the passage of the ducts of the gland to the areola. On the external surface of the skin, when the hair is removed, this areola can only be distinguished by the larger size of the orifices of the lacteal ducts, compared with those for the transmission of the hairs.

Fig. 200.



Mammary areola, Ornithorhynchus, natural size. (Owen, Phil. Trans. 1832.)

The orifices of the ducts thus grouped together form an oval spot, which in the female with the largest glands measured five lines in the long and three in the short diameter. In none of the specimens was the surface on which the ducts terminated raised in the slightest degree beyond the level of the surrounding integument.

Meckel was disposed to believe that the ducts terminated on a small eminence about the size of a millet-seed, but did not succeed in demonstrating the fact by injection of the ducts.*

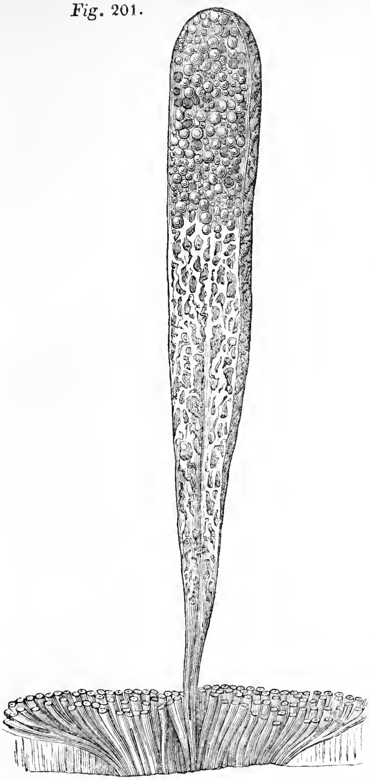
Not any of the specimens of Ornithorhynchus examined by me have presented a mammary eminence of any dimensions; on the contrary, I have succeeded in demonstrating the termination of the lacteal ducts on the flat areolar tract. Having in vain attempted to insert the smallest absorbent pipe into the mouths of these ducts, I thrust it into the extremity of one of the elongated lobes, and after a few unsuccessful efforts at length saw the mercury diffuse itself in minute globules through the parenchyma of the lobe, and at a distance of an inch it had evidently entered a central duct, down which it freely ran to the areola, where it escaped externally from one of the minute orifices just described. This process was repeated on most of the lobes with similar results, the greater part of them terminated by a single duct opening exteriorly and distinct from the rest, but in a few instances the ducts of two contiguous lobules united into one, and in these cases the mercury returned by the anastomosing duct and penetrated the substance of the other lobe as freely as that into which the pipe had been inserted.

Some of the lobes injected by the reflux of the mercury through the duct, and of which it was more certain that the glandular structure and not the cellular membrane was filled, were dried, and various sections were submitted to microscopical examination. At the greater extremity they are minutely cellular, the cells communicating with each other, and elongating as the lobule grows narrower, first at the centre, so as to form apparently minute tortuous tubes, which tend towards and terminate in a larger central canal, or receptacle, from which the excretory duct is continued. On making a section of the corium through the middle of the areola the ducts are seen to converge slightly to the external surface, but there is no inverted or concealed nipple at this part, as in the Kangaroo. (*Fig.* 201 is a sketch of a magnified view of this section, with the section of one of the dried and injected lobules.)

Thus, prior to and independently of any direct observation of the secretion of the abdominal glands, the anatomical facts brought to bear upon their disputed function were indubitably more favourable to the opinion of the German than of the French Professor; for, 1st, the glands are confined to the female, and vary in degree of development at different periods in individuals of equal size, attaining in some an enormous development; 2nd, the secretion is conveyed outwardly by means of numerous long and narrow ducts,

* Meckel writes: "Ductuli excretorii, maxime attenuati, in glandulæ medio extrorsum aperiuntur. Quamvis neque setas, neque mercuriam per ductus, et per se, ut monui, angustissimos, et spiritu vini contractos, et fluido concreto repletos, trajicere potuerim, area tamen indicatur in cute. Quamvis pili hanc partem tegant, apparet tamen, hos si abstuleris, plaga, quinque circiter lineas longa, tres lata, foraminulis, iis, e quibus pili egrediuntur, majoribus, nigris, circiter octoginta stipata, forsan ductuum excretorium orificiis. Præterea in hujus medio depressiuncula duarum linearum diametri adest, pilis destituta, sed eminentiunculis inæqualis, inter quas præcipue una, milii granum haud æquans, reliquas antecellit. Hæ sine dubio papillæ et ductuum orificia sunt."—Loc. cit. p. 54.

Fig. 201.



Terminal ducts, and lobe of mammary gland, injected; twice natural size.

strongly implying its fluid nature, and most contrary to the mode in which odorous substances are excreted; 3rd, the excretory orifices are by no means extended over so wide a space, in proportion, as in the Shrew, but collected into a point which we know to be not disproportionate to the size of the mouth of the young animal, and this point is situated in a part of the body convenient for the transmission of a lacteal secretion from the mother to her offspring.

Compared with an ordinary mammary gland, that of the Ornithorhynchus differs chiefly in the absence of the nipple, and, consequently, of the surrounding vascular structure necessary for its erection. But the remarkable modification of the mouth in the young Ornithorhynchus removes much of the difficulty which previously attached itself to the idea of the possibility of an animal with a beak obtaining its nutriment by suction. The width of the mouth in the smallest observed Ornithorhynchus corresponds with the size of the mammary areola; and the broad tongue, extending to the apices of the broad, short, and soft jaws, with the fold of integument continued across the angle of the mouth, are all modifications which prepare us to admit such a co-adaptation of the mouth of the young to the mammary outlet of the parent, as, with the combined actions of suction in the recipient, and compression of the gland in the expellent, to effect this essentially Mammalian mode of nourishment.

We may presume that a corresponding modification of the mouth of the new-born animal obtains in the Echidna, since the mammary glands in this Monotreme* correspond in structure, and mode of termination of the excretory ducts, with those of the Ornithorhynchus.

As yet the secretion of the mammary glands of the Echidna has not been observed; but that of the Ornithorhynchus has been detected not only in the stomach of the young (*ante* p. 401), but oozing from the lacteal pores of the female, and by more than one competent observer.† Mr. George Bennett, describing his dissection of a female Ornithorhynchus shot at Mundoona, New South Wales, on the 14th of November, the day before his arrival at that place, and which "had evidently just produced her young," and had very large mammary glands, thus records his observation of their secretion. "The glands were very vascular on the surface, the mammary artery ramifying over them in a most beautiful and distinct manner. The fur still covered that portion of the integument on which the ducts terminated, and there was no appearance of a projecting nipple." "How different was the appearance in the recent state of this mammary gland from that which I had previously seen at the Royal College of Surgeons, in a specimen long preserved in spirits, in which I had the opportunity of witnessing the injection of the ducts with mercury by my friend Mr. Owen, the mercury exuding, as I have seen the milk from the similar ducts, upon the integuments."—*Zoological Transactions*, vol. i. p. 251. In a female Ornithorhynchus, which with her two full-furred young were captured alive by Mr. Bennett on the 28th of December, he says, "The milk that could be expressed from the glands was but trifling in quantity; and, in the mother of these young animals, such would have been expected to be the case, for they were capable of feeding upon more substantial diet."—*Ibid.* p. 254.

Crural gland and spur.‡—This remarkable

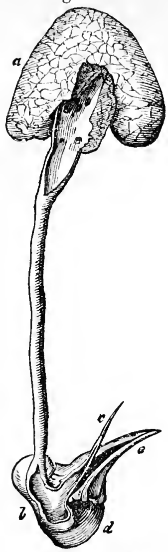
* See Phil. Trans. 1832, p. 537, pl. xvii., figs. 2 and 3.

† Hon. Lauderdale Maule, Proc. Zool. Society, part ii. p. 145. G. Bennett, Esq. ib. part i. p. 82. Part ii. p. 141-11.

‡ Meckel, loc. cit. p. 54, calls this peculiar sexual gland 'femoral,' observing, "ne ipso nomine de functione judicium proferam, forsan retrahendam, hoc nomen à situ impono." As, however, the femoral position is peculiar to the Ornithorhynchus, the gland being popliteal in the Echidna, I prefer a name derived from the word 'crus,' which has a more extended signification to the whole hinder extremity.

apparatus in the Monotrematous quadrupeds must be classed with the accessory organs of generation in the same category with the antlers of Deer, the spurs of the Cock, the claspers of the Shark, and other peculiar characteristics of the male sex. It has been already shown, in the description of the young Ornithorhynchus, that the external parts of the apparatus are not so developed as to distinguish the sex at that immature period; a small spur, concealed in a cavity or socket of the integument covering the heel, the bottom of which closely adheres to the accessory tarsal ossicle, exists in both sexes; a magnified view of the part in the young female is given at *fig.* 197. As the young animal advances to maturity the cutaneous socket increases in width and depth in the female, but without any corresponding growth of the rudimentary spur, of which in aged female Ornithorhynchi sometimes no trace remains. In the male Ornithorhynchus the tarsal spur soon begins to rise above the socket, and finally attains a length of ten lines with a basal breadth of five lines, apparently everting the tegumentary socket in the progress of its growth. The spur (*fig.* 173, K, *e*; *fig.* 202, *e*) consists of a firm semitransparent horn-like substance: it is conical, slightly bent, and terminated by a sharp point; its base is expanded, and notched at the margin for the implantation of the ligaments which connect the spur with the accessory flat tarsal bone (*os basilare*, Meckel,) (*fig.* 173, K, *d*; *fig.* 202, *d*.) The base of the spur is covered by a thin vascular integument. The spur is traversed by a canal which commences at the centre of the base and terminates by a fine longitudinal slit, about one line distant from the point, closely resembling in this respect the canal that traverses the poison fang of the venomous snake.* Like that canal also the spur of the male Monotreme is subservient to the transmission into the wounds it may inflict of the secretion of a peculiar gland.

Fig. 202.



Crural gland and spur, male Ornithorhynchus. (Meckel.)

This gland (*a*, *fig.* 202) is situated in the Ornithorhynchus at the back part of the thigh, between the femur and the long process from the head of the fibula, covered by the integument and the cutaneous muscle. It is of a triangular or reniform figure, convex above, concave below, or towards the leg; from twelve to fourteen lines in length, seven or eight lines broad, and three or four lines thick, with a smooth exterior, invested by a thin capsule, on the removal of which the gland may easily be divided into a number of small lobes. Its intimate structure, as displayed by a successful injection of mercury, is minutely cellular, like that of the glandula Harderi of the hare or goose, but with the ultimate secerning cells more minute; the excretory duct is continued from the concave side of the gland, and small clusters of vesicles are developed from parts of its expanded commencement.* The duct, (*fig.* 180, L,) which is about a line in width and with pretty strong tunics, descends straight down the back of the leg, covered by the flexor muscles and posterior tibial nerve, to the posterior part of the tarsus, where it suddenly expands into a vesicle (*b*, *fig.* 202) about three lines in diameter; the vesicle is applied to the base of the spur, and a minute duct (*c*, *fig.* 202) is continued from it into the canal which traverses the spur.

The tarsal perforated spur and its glandular apparatus are both relatively smaller in the male Echidna than in the Ornithorhynchus. The gland is situated lower down, in the popliteal region, between the insertions of the deep-seated fasciculi of the adductor femoris and the origins of the gastrocnemius; it is of subspherical form, about the size of a pea, with a smooth exterior; the excretory duct, wide at the commencement, soon contracts into a filamentary canal, which again enlarges to form a small reservoir for the secretion just above the base of the spur.

The true nature and use of this apparatus has not yet been determined. Its close analogy with the poison apparatus in other animals obviously suggests the idea of a corresponding function, but no well authenticated case of symptoms of poisoning consequent upon a wound inflicted by the spur has been recorded. It seems on the contrary that the Ornithorhynchus possesses not the instinct of availing itself of a weapon so formidable, as upon this theory the spur must be, when attacked or annoyed. Mr. George Bennett tried the following experiment with a full grown wounded but lively male Ornithorhynchus:—" I commenced by placing my hands in such a manner, when seizing the animal, as to enable it, from the direction of its spurs, to use them with effect; the result was that the animal made strenuous efforts to escape, and in these efforts scratched my hands a little with the hind claws, and even, in consequence of the position in which I held it, with the spur also. But although seized so roughly, it neither darted the spur into my hand nor did it even make an attempt so to do. As, however, it had been stated that the creature throws itself on the back when it uses this weapon, (a circumstance not very

* De Blainville in Bulletin de la Société Philomathique, 1817.

* Müller, De Glandularum penit. Struct. p. 43, tab. ii. fig. 10.

probable to those who have any knowledge of the animal,) I tried it also in that position; but though it struggled to regain its former posture, no use was made of the hind claw. I tried several other methods of effecting the object I had in view; but as all proved futile, I am convinced that some other use must be found for the spur than as an offensive weapon. I have had several subsequent opportunities of repeating the experiments with animals not in a wounded state, and the results have been the same."*

Evidence to a like effect is given by the zoologists of the French expedition in the Astrolabe, in reference to the male Echidna.† An objection to the theory of the spur and gland being a defensive apparatus is their absence in the female.

Since then this apparatus forms a sexual character, it may be presumed that its function is connected with that of generation. Whether the spur be a weapon for combat among the males,—or, like the spiculum amoris of the Snail, be used to excite the female, the injected secretion being an additional stimulus,—or whether the spur be mechanically useful in retaining the female during the coitus,—are conjectures which must be verified or disproved by actual observation.

MONSTROSITY.—See TERATOLOGY.

MOTION ANIMAL, ANIMAL DYNAMICS, LOCO-MOTION, OR PROGRESSIVE MOTION OF ANIMALS.—Amongst the infinite number of objects presented by the Deity to our contemplation in the sublime spectacle of the universe, there are none, relating to the economy of animal life, more important in their consequences, more calculated to awaken inquiry, or deserving of more profound research, than the phenomena of progressive motion in man and animals.

Life, in virtue of which animated beings possess sensation and exhibit the play of the vegetative functions, endows the muscular system with contractility, and is the fundamental cause of all the motor power of animals.

The theory of the progressive motion of animals presents a most extensive field for anatomical and physiological inquiry, far too extensive indeed for the space here allotted to this subject; it will therefore be treated only in outline. The automatic, and several of the voluntary motions which belong to the vegetative functions of the animal economy, though derived from the same source as those of progressive motion, will not be included in this investigation.

The theory of locomotion relates to those mechanical functions by which animals are capable of changing their relative positions or distances with respect to surrounding objects supposed to be stationary or fixed.

The locomotive organs of the higher animals are composed of a system of levers of various forms, orders, and dimensions, so united or articulated at the joints as to give them the requisite mobility as well as direction of motion. The fulcra to these levers are the earth, the air, or the water; the active agents of motion are the muscles which constitute a complex system of contractile organs, firmly attached to the levers, whereof the points of connexion, amount of contraction, and direction of force, communicate to the levers, to which they are firmly attached, all the movements necessary for progression.

The progression of some animals, such as the Annelida and Ophidian Reptiles, is effected by the alternate contraction or flexion and elongation, or by undulatory movements of the body; in others, as Bipeds, Quadrupeds, Fishes, Birds, &c., by the alternate approximation and angular separation of the levers which form the organs of progression. These principles apply to animals, whether their levers are represented by wings, fins, or legs, and whether the progression is effected on solids, in water, or in the air.

The various modes of animal progression

are swimming, flying, crawling, climbing, leaping, running, walking, &c. The consideration of these diversified methods of progression involves the theory of the motion of bodies in general, of the lever, the pulley, the centre of gravity, specific gravity, and the resistance of fluids, &c.; and, as we shall have occasion for constant reference to the mechanical principles connected with these subjects, they will be first discussed; but for the convenience of those who are unacquainted with the algebraic method of computation and analysis, the latter will generally be separated from the text.

Fundamental Axioms. — First, every body continues in a state of rest or of uniform motion in a right line until a change is effected by the agency of some mechanical force. Secondly, any change effected in the quiescence or motion of a body is in the direction of the force impressed, and is proportional to it in quantity. Thirdly, reaction is always equal and contrary to action, or the mutual actions of two bodies upon each other are always equal and in opposite directions.

Thus if M (*fig.* 203) be a particle of matter free to move in any direction, and if the lines MA, MB, represent the intensity of two forces

Fig. 203.

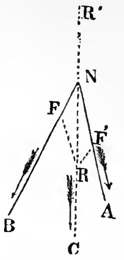
acting on it in the direction MC, the particle M will move towards C by the combined action of the two forces, and it will require a force in the direction of CM, equal to MA+MB to keep it in a state of rest: but if MA and MB (*fig.* 204) represent the intensities and directions of two forces acting on the particle M in opposite directions, if MA be

Fig. 204.

greater than MB, the particle M will be moved towards A by the difference of these two forces, and it will require a force equal to that difference to keep it at rest.

The composition and resolution of forces.— In the composition of forces it is proposed to find the resultant, arising from any number or system of forces acting upon a given point. The resolution of forces, which is the converse of the former process, consists in discovering what forces acting in given directions would combine to produce a given resultant: Thus, if there be two forces F F′ (*fig.* 205), whose directions and magnitudes are represented by F N, F′ N, and if FR, F′R be drawn respectively parallel to F′N, FN, then by the composition of forces we find the magnitude and direction of the equivalent or resultant of these two forces to be RN, and conversely it may be resolved into a pair of forces as RF, RF′ represented by the adjacent sides of any parallelogram, of

Fig. 205.



which RN is the diagonal, and consequently into an indefinite number of such pairs.* *This construction is called the parallelogram of forces.*

The resultant of any number of forces meeting in a common point may be ascertained thus: first, let the resultant of any two forces be found as before, and substitute this one force for the two components producing it; then combine this new force with one of the remaining forces, and continue this process until all the forces are reduced to a single force, which is the resultant sought. The following geometrical solution will render the subject more apparent: let P, P′, P″, &c. (*fig.* 206) represent a number of forces meeting in the common point A, and let A P, A P′, A P″ be proportional to these forces respectively: through P draw PR equal and parallel to AP′, and through R draw RR′ equal and parallel to AP″, and through R′ draw R′ R″ equal and parallel to A P‴; join A R″, which represents the resultant of the four forces A P, AP′, AP″, AP‴. A similar operation will serve for any number of forces. This figure is denominated the *polygon of forces.* If the directions of three forces are rectangular, and in different planes, the resultant may be found as follows: let P C, P C′, P C″, (*fig.* 207) be the intensities and directions of three forces, complete the parallelopiped BD; then the forces PC, PC′ have P *r* for an equivalent, therefore P *r* may be substituted for these two forces; and by compounding the forces PC″, P *r*, we get PR the diagonal of the parallelopiped BD *r* for an equivalent to the three forces. This construction is called the *parallelopipedon of forces.*†

An equilibrium cannot subsist between any two forces acting upon a point of matter, if the lines representing the directions of the forces be inclined to each other at any angle; but a third force, equivalent to their resultant and in an oppo-

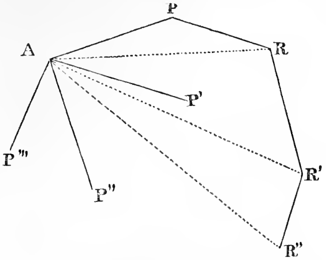
* Vide Gregory, vol. iii. ch. ii. p. 23.

† From the same construction the resultant of a system of forces may be found, disposed in different planes by the method of rectangular co-ordinates: let $P\,C = x$, $P\,C' = y$, $P\,C'' = z$, (*fig.* 207), by the 47 Euc. Lib. I. we have $Pr^2 = PC^2 + Cr^2 = x^2 + y^2$, and $P\,R^2 = Pr^2 + r\,R^2 = x^2 + y^2 + z^2$, whence the resultant $P\,R = \sqrt{x^2 + y^2 + z^2}$. The position of the resultant is thus determined; let r, r', r'' denote the unknown angles formed by the direction of the resultant with each of the co-ordinates, and R cos. r, R cos. r', R cos. r'' will represent the equivalents of the resultant in the several directions of the axes, hence we have R cos. $r = x$, R cos. $r' = y$, R cos $r'' = z$, ∴

$$\text{Cos. } r = \frac{x}{R}, \text{ cos. } r' = \frac{y}{R} \text{ cos. } r'' = \frac{z}{R}.$$

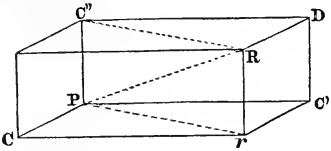
site direction to it, will produce an equilibrium.

Fig. 206.



Let N (*fig.* 205) be the point acted upon by any two forces N F, N F′, which form an angle F N F′, and the line N R their resultant, which will draw the point in the direction N R. But if a third force N R′, equal and opposite to N R, be applied, it will destroy the motion in N R, and the point N will remain at rest by the simultaneous action of the three forces N R′, N F, N F′.

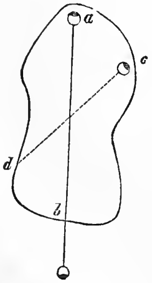
Fig. 207.



Centre of gravity.—The centre of gravity of any body is a point about which, if acted upon only by the force of gravity, it will balance itself in all positions; or, it is a point which, if supported, the body will be supported however it may be situated in other respects; and hence the effects produced by or upon any body are the same as if its whole mass were collected into its centre of gravity.

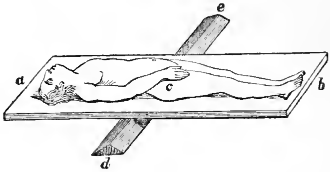
To find the centre of gravity of any plane body mechanically, let the plane *a e d b* (*fig.* 208) be suspended freely by a string from the point *a*, to which a plumb-line *a b* is also attached — the latter will coincide with the vertical line *a b*, which is to be marked with a pencil: then suspend the plane and plumb-line from a second point *e*, when the plumb-line will hang vertically in the line *e d*, intersecting *a b* in *c*, the point *c* will be the centre of gravity of the plane.

Fig. 208.



To find the distance of the head and feet from the centre of gravity of the human body in a horizontal position; balance the body placed upon a plane *a b* on a triangular prism *d e*, as in *fig.* 209; then draw a line on the plane

Fig. 209.



close to the edge of the prism; again balance the body in another position and draw a line as before, the vertical line passing through *c*, the intersection of these lines will pass through the centre of gravity.

After the plan of Borelli, Weber balanced a plank across a horizontal edge, and stretched upon it the body of a living man: when the whole was in a state of equilibrium, in which the method of double weighing was adopted, by accurate measurements he found the total length of the body

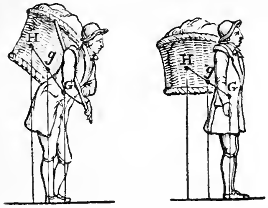
	m.m.	in.
	= 1669.2 =	65.30853
the distance of the centre of gravity below the vertex	= 721.5 =	28.406455
above the sole of the foot	= 947.7 =	37.310949
above the transverse axes of the hip-joints	= 87.7 =	3.454729
above the promontory of the sacrum	= 8.7 =	0.341519

As the horizontal plane of the centre of gravity lies between three-tenths and four-tenths of an inch above the promontory of the sacrum, it must traverse the sacro-lumbar articulation which is intersected by the mesial plane, because the body is symmetrical, and by the transverse vertical plane, the sacro-lumbar articulation must, therefore, contain the common *point of intersection* of all three planes, which coincides with the position of the centre of gravity of the body when standing; but this point varies in different individuals in proportion to the difference of the weight of the trunk to that of the legs, as well as by any change of the position of the limbs.

The centres of gravity of particular figures may be found geometrically and analytically, as shewn in mechanical treatises; but these methods require computations too detailed for our limits.

The attitudes and motions of every animal are regulated by the positions of their centres of gravity, which, in a state of rest and not acted on by extraneous forces, must lie in vertical lines which pass through their bases of support. Thus, if *g* (*fig.* 210, A and B) be the common centre of gravity of two bodies whose respective centres of gravity are *g*, H, in A the whole mass will be supported, whilst in B it will fall over on the side of H.

A *Fig*. 210. B

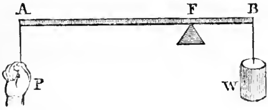


In most animals moving on solids, the centre is supported by variously adapted organs; during the flight of birds and insects it is suspended; but in fishes, which move in a fluid whose density is nearly equal to their specific gravity, the centre is acted upon equally in all directions.

The lever.—Levers are commonly divided into three kinds, according to the relative positions of the prop or fulcrum, the power, and the resistance, or weight. The straight lever of each order is equally balanced when the power multiplied by its distance from the fulcrum equals the weight, multiplied by its distance, or P the power, and W the weight, are in equilibrium when they are to each other in the inverse ratio of the arms of the lever, to which they are attached: the pressure on the fulcrum however varies.

In straight levers of the *first kind*, the fulcrum is between the power and the resistance, as in *fig*. 211, where F is the fulcrum of the

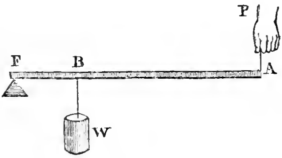
Fig. 211.



lever A B; P is the power, and W the weight or resistance. We have $P : W :: BF : AF$, hence $P.AF = W.BF$, and the pressure on the fulcrum is both the power and resistance, or $P+W$.

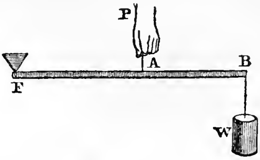
In the second order of levers (*fig*. 212) the resistance is between the fulcrum and the power; and, as before, $P : W :: BF : AF$, but the pressure of the fulcrum is equal to $W-P$, or the weight less the power.

Fig. 212.



In the third order of lever the power acts between the prop and the resistance (*fig*. 213),

Fig. 213.



where also $P : W :: BF : AF$, and the pressure on the fulcrum is $P-W$, or the power less the weight.

In the preceding computations the weight of the lever itself is neglected for the sake of simplicity, but it obviously forms a part of the elements under consideration, especially with reference to the arms and legs of animals.

To include the weight of the lever we have the following equations: $P.AF + \overline{AF}.\frac{1}{2}AF = W.BF + \overline{BF}.\frac{1}{2}BF$; in the first order where $\overline{AF}$ and $\overline{BF}$ represent the weights of these portions of the lever respectively. Similarly, in the second order $P.AF = W.BF + \overline{AF}.\frac{AF}{2}$, and in the third order $P.AF = W.BF + \overline{BF}.\frac{BF}{2}$.

In this outline of the theory of the lever, the forces have been considered as acting vertically, or parallel to the direction of the force of gravity.

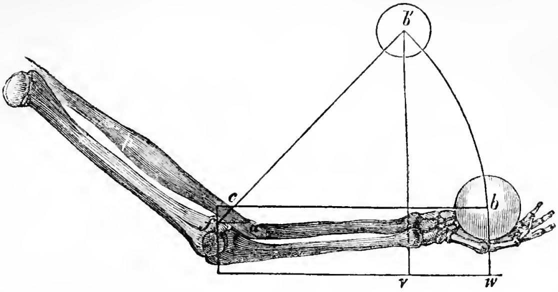
The head moving backwards and forwards on the atlas acts on the principle of the first kind of lever, the fulcrum being placed between the power and the resistance. The tibia resting on the astragalus acts on the principle of the second order of lever, when the heel is raised by the tendo Achillis, the resistance being between the power and the fulcrum, or between the heel and the toes.

In lifting a weight by the hand and bending the elbow-joint, as in *fig*. 214, in which *p* the power, or biceps muscle is inserted at *a* between the fulcrum *f*, and the resistance *w* or *b*, we act on the principle of the third order of lever.

In the latter case, however, the power, instead of acting vertically, is applied obliquely, and the lever, instead of simply resting on the fulcrum, turns upon a point at *f*, *fig*. 214. Instead, therefore, of estimating the values of *p* and *w* as before, according to their reciprocal distances from the fulcrum, we resolve each of them into two other forces by perpendiculars drawn from the fulcrum *f* to the directions of the forces *p* and *w*. Thus, in *fig*. 214, *p* will not be to *w* as *b f* to *a f*, but as the perpendiculars from *f* on the vertical line through *b* to that on *a c* the direction of the insertion of the muscle.

The pulley.—The principles of the simple pulley are introduced into the mechanism of animals for the production of motion, and to change the directions of the motions of several organs in reference to that of the tendons

Fig. 214.



moving them. There are no examples of the compound pulley in animal structures.

We recognise the simple pulley in the transmission of the tendons of the peronei muscles through the groove of the external malleolus of the human ankle-joint, in the tendon of the obturator internus gliding through the groove in the os ischii, in the tendon of the circumflexus palati passing through the hamular process of the sphenoid bone, in the tendon of the obliquus superior gliding through the ring attached to the frontal bone, and in several other instances where a change of the directions of the limbs results from tendons passing over joints, through grooves in bones, or under ligaments, by which the muscles are capable of producing effects on distant organs without disturbing the symmetry of the body, an effect which, owing to the limited power of contraction in the muscles, could be accomplished in no other way.

Of uniform motion.—If a body move constantly in the same manner, or if it pass over equal spaces in equal periods of time, its motion is uniform. The velocity of a body moving uniformly is measured by the space through which it passes in a given time.*

The velocities generated or impressed on different masses by the same force are reciprocally as the masses.†

Motion uniformly varied.—When the motion of a body is uniformly accelerated, the space it passes through during any time whatever is proportional to the square of the time.

In the leaping, jumping, or springing, of animals in any direction, (except the vertical,) the paths they describe in their transit from one point to another in the plane of motion are parabolic curves.

The legs move by the force of gravity as a pendulum.—To the many instances already recognised of the connexions subsisting between the functions of living animals and the physical sciences, another remarkable contribution has been recently added by the Professors Weber, whose experimental researches satisfactorily demonstrate that the swinging forwards of the legs of animals in progressive motion obeys the same laws as those of the periodic oscillations of the pendulum. In order to ascertain these relations, MM. Weber instituted a series of experiments upon legs of given lengths, both in the living and dead subject, and under variously modified circumstances. Having removed a leg from the trunk at the hip-joint, and suspended it by a short thread that it might move as if upon the axis of the head of the femur; upon giving it an impulse they found it oscillated nearly in the same time as in the living state. They next communicated a vibratory motion to a leg suspended to the acetabulum by the ligaments of the hip-joint only, the muscles having been previously cut through: in this experiment the oscillatory movements were rather less than in the preceding. The oscillations of the leg of a dead person after the rigidity of the muscles had subsided, were still further diminished. On comparing the durations of the vibrations of the legs in these several states with those of the living, they found their periods nearly equal or in the following proportions.

No.	Length of leg. in metres.*	Half duration of oscillation.	
	m	″	
1	0.831	0.370	An exarticulated freely suspended leg.
2	0.866	0.371	The same.
3	0.831	0.355	A leg suspended to the trunk by the ligaments only, the muscles of the hip joint having been cut through.
4	0.831	0.355	A leg of the dead body in its natural state.
5	0.860	0.346	A living leg swinging uninfluenced by the action of muscles.
6	0.860	0.322	A living leg walking on the heel.
7	0.860	0.323	A living leg walking on the ball of the foot.

* A metre = 3.2808992 feet.
A millimetre = 0.03987 inch.

* Thus if v be the space passed over by the body in an unit of time, that space $\times$ by t, or $t\ v$ will be the space s passes over in t units, that is,

$$s = t\,v \ldots\ldots\ldots\ldots (1).$$

† If a force communicates a velocity v to a mass m, and a velocity v' to a mass m', then we have

$$mv = m'\,v' \ldots\ldots\ldots\ldots (2).$$

Generally, if f be the accelerating force, the space

$$s = \tfrac{1}{2} f t^2, \ldots\ldots\ldots\ldots (3).$$

and

$$s = \frac{tv}{2} \ldots\ldots\ldots\ldots (4).$$

From this table it appears conclusive that no muscular force is employed or required to propel the leg forwards after it has been raised and bent by the flexor muscles, and that the force of the earth's gravity alone on the leg is sufficient to accomplish that purpose. The difference found between the oscillation of the legs in the living and the dead body is very small, and is attributed by those authors to the elasticity of the ligaments connecting the leg to the trunk, and some trifling differences in the length of the legs, but decidedly not to muscular action. An application of the principles of the pendulum to the legs of animals moving in a vertical plane shows that the durations of their periodic oscillations must be respectively *as the square roots* of their lengths,* estimated by the distance of the centre of oscillation; or the time of a complete oscillation of any leg from behind forwards when influenced only by gravity is to the time in which a heavy body would fall through half the length of the leg, considered as a compound pendulum, as the circumference of a circle is to its diameter.

It further results from the periodic movements of the legs being subordinate to the force of gravity, that the same individual would necessarily walk slower as he approached the equator, and quicker as he approached the poles, all other circumstances being equal. For example, let us suppose any two persons to be walking in different latitudes, whose legs are of unequal length, and acted on by unequal gravitating forces, then by the theory of the pendulum the time of the swinging forward of their legs respectively will be as the square roots of their lengths directly and as the square roots of the gravitating forces in those latitudes inversely.†

Mechanical effects of fluids on animals immersed in them.—When a body is immersed in any fluid whatever, it will lose as much of its weight relatively as is equal to the weight of the fluid it displaces. In order to ascertain whether an animal will sink or swim, or be sustained without the aid of muscular force, or to estimate the amount of force required that the animal may either sink or float in water, or fly in the air, it will be necessary to have recourse to the specific gravities both of the animal and of the fluid in which it is placed.

The specific gravities or comparative weights of different substances are the respective weights of equal volumes of those substances.* When any solid body is immersed in a fluid and left to itself, it will sink if its specific gravity is greater than that of the fluid; but if its specific gravity be less than that of the fluid, it will rise to the surface and be sustained there; and when the specific gravity of the solid and fluid are equal, the body will remain stationary wherever it is placed. When the weight of any body taken in a fluid is subtracted from its weight out of the fluid, the difference is the weight of a volume of the fluid equal to that of the solid; this is to its weight in air, as the specific gravity of the fluid to that of the solid; so that generally the specific gravities of solid bodies are as their weights in the air directly, and their losses in water or any other fluid inversely.†

The specific gravity of air, water, and mercury, when the barometer stands at 30 in. and the thermometer at 55°, being to each other as $1\frac{2}{3}$, 1000, 13600, it results that all those animals whose specific gravities approximate to that of water are nearly 1000 times heavier than air, and more than thirteen times lighter than mercury, and consequently animals that would sink and perish in water could walk on the surface of mercury.

The human body in a healthy state, with the chest filled with air, is specifically lighter than water, and its sinking generally depends upon the air in the lungs escaping under the pressure of water upon its immersion. Dr. Arnott remarks that if this truth were generally and familiarly understood, it would lead to the saving of more lives than all the mechanical life-preservers which man's ingenuity will ever contrive.

Atmospheric pressure produces a great variety of mechanical effects on animal structures. If we estimate the surface of a man to be equal to 2000 square inches, the pressure of the atmosphere on his body with the barometer at 30 in. will amount to 30,000 lbs., or about 15 tons; when the barometer falls from 30 to 27 inches, the pressure is reduced from 15 to $13\frac{1}{2}$ tons; we need not, therefore, be surprised that variations of atmospheric pressure should be attended with corresponding sensations in living animals.

The pressure of the atmosphere enables some animals (as we shall subsequently prove) to fix themselves to rocks with great force, to walk up the surfaces of glass windows, to sustain themselves in an inverted position on the

* Let l and l' equal the lengths of any two pendulums, t t' the times of vibrations, g the force of gravity, π to ι the ratio of the circumference of a circle to its diameter, then

$$t = \pi \sqrt{\frac{l}{g}} \text{ and } t' = \pi \sqrt{\frac{l'}{g}},$$

$$\therefore t : t' :: \sqrt{l} : \sqrt{l'} \ldots\ldots (5.)$$

† For as $t = \pi \sqrt{\frac{l}{g}}$, and $t' = \pi \sqrt{\frac{l'}{g'}}$,

$$\text{hence } t : t' :: \sqrt{\frac{l}{g}} : \sqrt{\frac{l'}{g'}} \ldots\ldots\ldots\ldots (6.)$$

* If W, w are the weights of two substances, V, v their volumes, S, s their specific gravities, then

$$S : s :: \frac{W}{V} : \frac{w}{v}.$$

† Let W = the weight of the body in air, W′ = its weight in water or any other fluid, S = the specific gravity of the solid, s = the specific gravity of the fluid, then we shall have the following proportions;

$$W - W' : W :: s : S;$$

$$\text{hence} \quad s = \frac{W - W'}{W} S \ldots\ldots\ldots (7.)$$

$$\text{and} \quad S = \frac{W}{W - W'} s \ldots\ldots\ldots (8)$$

ceilings of rooms in opposition to the force of gravity, and to hold the mechanism of the joints together with a force proportional to their respective areas.

The air being elastic, its density decreases as the elevations above the earth's surface increase, and when the heights increase in an arithmetical progression the densities decrease in a geometrical progression; hence, in the flight of birds, the weight of air which they displace, and the effective force of their wings must continually vary with every change of elevation.

Animals moving in water at various depths are not subjected to the same variations of density that are experienced in air, since water, being nearly incompressible, suffers no sensible change of volume at the greatest depths of the ocean; but although the density remains nearly constant, the pressure increases with the depth, being equivalent to about one pound on the square inch for every two feet. The specific gravity of water being from 800 to 1000 times greater than air, its pressure becomes very great at the known depths to which many fishes and cetaceous animals descend.

Resistance of fluids.—Animals moving in air and water experience in those media a sensible resistance, which is greater or less in proportion to the density and tenacity of the fluid, and the figure, superficies, and velocity of the animal.

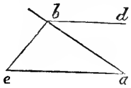
An inquiry into the amount and nature of the resistance of air and water to the progression of animals will also furnish the data for estimating the proportional values of those fluids acting as fulcra to their locomotive organs, whether they be fins, wings, or other forms of lever.

The motions of air and water, and their directions, exercise very important influences over velocity resulting from muscular action.

The resistance of a plane moving perpendicularly to itself in a fluid, equals the weight of a column of the fluid of which the base is equal to the plane, and the altitude to the depth through which a body would fall to acquire by gravity the velocity of the plane.*

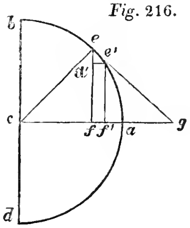
If the direction† of the motion, instead of being perpendicular to the plane, as before supposed, be inclined to it at any angle, the resistance will be diminished in the *triplicate* ratio of the sine of the angle of inclination.

Fig. 215.



When a body is terminated by a curved surface generated by the revolution of a plane round its axis, and moves parallel to that axis, the amount of resistance may be obtained by the formulæ and analysis subjoined.*

Fig. 216.



But the forms of animals, though symmetrical, can rarely be considered as mathematically regular figures, and consequently many of the data for calculating the resistance to their movements must be derived from experiment.

Passive organs of locomotion. Bones.—The solid framework, or skeleton of animals which supports and protects their more delicate tissues, whether chemically composed of entomoline, carbonate, or phosphate of lime; whether placed internally or externally; or whatever may be its form or dimensions, presents levers and fulcra for the action of the muscular system, in all animals furnished with earthy solids for their support, and possessing locomotive power.

The form, strength, density, and elasticity of skeletons vary in relation to the bulk and locomotive power of the animal, and to the media in which it is destined to move.

* Let a represent the area of the plane, v the velocity, p the specific gravity of the fluid, then the height due to the velocity being $\frac{v^2}{2g}$, the whole resistance is

$$a\,p\frac{v^2}{2g}\ \ldots\ldots\ldots\ldots\ldots\ldots(9.)$$

hence, cæteris paribus, the resistance is as the square of the velocity.

† Let A B (*fig.* 215) be the plane, and B D the direction of its motion, A B D the angle whose sine is s, the number of particles which strike the plane, as well as the force of each particle, will be diminished in the ratio of 1 to s, therefore the whole resistance will be diminished in the ratio of $1 : s^2$, but the effective part of the resistance being perpendicular to the plane, the whole resistance in the direction A E is to the effective part in the direction B E perpendicular to A B, as A E and B E, or as 1 to s. Hence the whole resistance in the direction of the motion will be diminished in the ratio of $1 : s^3$, and will therefore be

$$\frac{a\,p\,v^2\,s^3}{2g}\ \ldots\ldots\ldots\ldots\ldots(10.)$$

* Let $b\,e\,a\,d$ (*fig.* 216) be the section through the axis $c\,a$ of the body whose motion is in the direction of $c\,a$, draw the tangent $e\,g$ to any point of the curve meeting the axis produced in g, draw the ordinates $e\,f$ and $e'\,f'$ indefinitely near each other, also draw $e'\,d'$ parallel to $g\,c$, then let $c\,f = x$, $e\,f = y$, $b\,e = z$, and s the sine of the angle g to the radius 1; then $2\,\pi\,y$ is the circumference of the circle whose radius is $e\,f$ and $2\,\pi\,y \times e\,e'$ or $2\,\pi\,y\,d\,z$ is the surface described by $e'\,e$ in its revolution about the axis $c\,a$, which is the quantity represented by (a) in the preceding note, therefore

$$\frac{p\,v^2\,s^3}{2g}\;2\,\pi\,y\,d\,z,\ \text{or}\ \frac{\pi\,p\,v^2 s^3}{g}\,y\,d\,z\ \ldots(11.)$$

will be the resistance on that ring or the differential of the resistance to the body whatever its figure may be.—(See Gregory's Mechanics, chap. v. p. 521.)

The number of moveable articulations in a skeleton determines the degree of its mobility within itself; and the kind and number of these articulations of the locomotive organs determine the number and disposition of the muscles acting upon them. See ARTICULATION.

The strength, density, and elasticity of the external skeleton of animals have been but very partially investigated or made an object of either physiological or mechanical enquiry, notwithstanding their great importance in the animal economy generally, as well as their office in locomotion.

A superficial inspection, however, is sufficient to detect that the shells of those animals which reside constantly at the bottom of the sea, as the Astrea triduina, Phombus, &c. are more dense, and contain a greater number of calcareous laminæ than those which swim or float, either by means of specific organs of progression, such as the Ianthina vulgaris, the Lymnæ, and Hyalæa, or upon hydrostatic principles, as in the Nautilus, assisted, it is believed, by the siphon. Shells are formed with a design to resist the greatest external pressure, consistent with the least expenditure of materials, and with regard to the habits of the animal. The bones of vertebrated animals, especially those which are entirely terrestrial, are much more elastic, hard, and calculated by their chemical elements to bear the shocks and strains incident to terrestrial progression than those of the aquatic vertebrata; the bones of the latter being more fibrous and spongy in their texture, the skeleton is more soft and yielding.

The bones of the higher orders of vertebrata, such as the Mammalia, which are designed to afford large surfaces for the attachment of their powerful muscles of locomotion, are constructed in such a manner as to combine lightness with strength; therefore their surfaces are convex externally, concave within, and strengthened by ridges running across their discs: such are the forms of the scapular and iliac bones.

The long bones of the legs and arms of Mammalia are piled on each other endwise, forming a series of moveable columns, which in the standing position are directed vertically; these are designed to support the head, neck, and trunk, with all their contents and appendages, together with their own weight, and to elevate the trunk to some variable height above the plane of position.

It would indeed be a problem of no small difficulty, if it were proposed to an artist to erect a moveable column, composed of a definite number of rods, so united and inclined as to fulfil all the objects, for which the long bones of the extremities are designed when viewed only mechanically, and adapted to support the weight of the superincumbent organs, to present the lengthened dimensions necessary to raise the trunk often far above the plane of motion, the strength requisite to bear the shocks directed upon them both vertically and laterally, the symmetry of form and beauty of proportion corresponding to the outline and functions of other organs, their extremities being furnished with articulating surfaces for the joints, with ridges and protuberances for the attachment of muscles, and with levers adapted to perform all the varied offices of locomotion.

In quadrupeds, which have four osseous columns to support the superincumbent organs, the pressure of the trunk on each leg is only half that in bipeds; but owing to the horizontal inclination of the trunk and the projection of the neck and head, the anterior osseous pedestals have to sustain the largest proportion of the weight; and we consequently find that the angle formed by the bones of the anterior extremities at the joint are less, and the directions of the bones nearer the vertical plane in these than in the posterior: this arrangement is most conspicuous in the larger Ruminantia and Pachydermata, especially in the Elephant, Horse, &c. We may, therefore, readily perceive why the shafts of the long bones of the legs and arms of most Mammalia are partially hollow cylinders; the prismatic outline predominates in the Elephant and Megatherium.

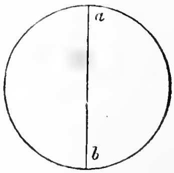
The weights which cylindrical or prismatic flexible columns will support perpendicularly when their bases and composition are equal is, according to Euler,* in the inverse ratio of the squares of their lengths, therefore if we take any bones, of similar materials and thickness, but of which the lengths are as 1, 2, 3, 4, 5, they will support weights without flexion relatively in the proportions 1, $\frac{1}{4}$, $\frac{1}{9}$, $\frac{1}{16}$, $\frac{1}{25}$, so that whilst the lengths increase in an arithmetical progression, the weights will decrease in a geometrical progression; the necessity, therefore, for dividing the columns which sustain the trunk by means of the joints, independently of the use of the latter for locomotion, is obvious.

According to Galileo, the power of a beam or bar to resist a fracture by a force acting laterally, is as the section of the beam, where the force is applied, multiplied into the distance of the centre of gravity of the section from the point or line where the fracture will end. By applying this principle to the case of bones, we deduce the following propositions, which must, however, be regarded only as approximations to the truth.

The lateral strength of two cylindrical bones of equal weight and length, of which one is hollow and the other solid, are to each other as the diameters of their transverse sections. Thus, let *a b*, *d e* (*fig.* 217, A, B,) be the section of the two bones: then the strength of the tube *d e* is to that of the solid *a b* as *d e* to *a b*.

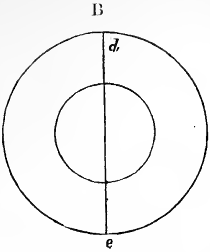
Fig. 217.

A



* De curvis elasticis, No. 37.

Fig. 217.



Upon the principle of this proposition, it was long since observed by Galileo that nature greatly augments, in a thousand ways, the strength of bodies without increasing their weight, and that if a wheat straw which supports the ear, that is heavier than the whole stalk, were made of the same quantity of matter, but solid, it would bend or break with far greater ease than it now does. The feathers of birds as well as the bones of animals present similar provision for the combination of strength, lightness, and economy of material. The strength of bones, however, cannot, as might possibly be inferred from the preceding proposition, be increased with the same quantities of matter indefinitely, because when the diameter of the tube exceeds certain dimensions it will become so thin and fragile as to break almost without offering any resistance.

The lateral strengths of prismatic bones of the same materials are as the areas of their sections and the distances of their centres of gravity directly; and their lengths and weights inversely.

From the deductions which may be drawn from the preceding proposition Galileo very justly concludes that "there are limits set to the magnitudes of the works of nature and art, and that the size of ships, palaces, and temples, trees and animals, cannot surpass certain dimensions; and he observes that large animals have neither the strength nor speed proportionate to their bulk, and if there were any terrestrial animals much larger than those we know, they could hardly move, and would be much more subject to the most serious accidents: and also that it is impossible for nature to give bones to men, horses, or other animals, if they were enlarged to immense heights so as to perform their offices proportionally unless the structure of bones were composed of materials much more firm and resisting, or that they were made of a thickness out of all proportion, which would render the figure and appearance of animals monstrous." Mr. Banks has found that an oak rod one inch thick, supported at each end, will break by its own weight at the length of 57.45 feet, and a similar one of iron at 38.223 feet; Emerson also found that the cohesive strength of bone is double that of oak, whilst its specific gravity is only to that of the latter as 1656 to 1170, or as 92 to 65. In the Megatherium and Elephant the length of the bones of the legs is small compared with their diameters, and consequently they possess greater comparative strength as columns in supporting their ponderous superstructures.

In the thigh bones of most animals an angle is formed by the head and neck of the bone with the axis of the body, which prevents the weight of the superstructure coming vertically upon the shaft, converts the bone into an elastic arch, and renders it capable of supporting the weight of the body in standing, leaping, and in falling from considerable altitudes.

Joints.—Where the limbs are designed to move to and fro simply in one plane, the ginglymoid or hinge-joint is applied; and where more extensive motions of the limbs are requisite, the enarthrodial, or ball and socket joint, is introduced. These two kinds of joints predominate in the locomotive organs of the animal kingdom. Though the ginglymoid joint restricts the movements of the limbs to one plane, yet it secures that precision of direction and firmness of step recognized in their motions, as well as the steadiness with which they support the trunk. The elbow, knee, and ankle-joints, in man more especially, though ginglymoid, are differently constituted and possess different degrees of mobility. The limbs revolving upon the elbow-joint move in concentric planes, whilst those articulated at the knee allow, according to Weber, a rocking motion upon each other; the ankle has the greatest latitude of motion of these three ginglymoid joints.

The enarthrodial joint has by far the most extensive power of motion, and is therefore selected for uniting the limbs to the trunk, as it is at the enarthrodial joints that the planes in which all the limbs move is determined.

The enarthrodial joints permit of the several motions of the limbs termed pronation, supination, flexion, extension, abduction, adduction, and revolution upon the axis of the limb or bone about a conical area, whose apex is the axis of the head of the bone, and base circumscribed by the distal extremity of the limb.

In consequence of the structure of the ankle-joint, the foot may be directed out of the plane of the leg's motion.

The limbs, in moving upon or about the heads of bones, describe arcs of circles, of which the centres of motion are the axes of the heads of the bones or the tubercles on which they revolve.

Ligaments.—The office of the ligaments with respect to locomotion is to restrict the degree of flexion, extension, and other motions of the limbs within definite limits.

The strength, form, elasticity, and points of attachment of ligaments are sufficient to effect the objects above mentioned; they are, however, destined mechanically to limit the motions rather than to expend their forces in supporting the weight of the limbs suspended beneath the joints to which they severally belong.

The influence of atmospheric pressure in supporting the limbs was first noticed by Dr.

Arnott, though it has been erroneously ascribed by Professor Müller to Weber. Subsequent experiments made by Dr. Todd, Mr. Wormald, and others, have fully established the mechanical influence of the air in keeping the mechanism of the joints together. The amount of atmospheric pressure on any joint depends upon the area or surface presented to its influence and the height of the barometer. The forces acting in opposition to the weight of the limb are the pressure of the air, and a force employed by the ligaments and muscles equal to the excess of the weight of the limb, if any, above that of the pressure of the atmosphere. According to Weber the atmospheric pressure on the hip-joint of a man is about 26 pounds. The pressure on the knee-joint is estimated by Dr. Arnott at 60 pounds. This estimate agrees with our measurement of the area of the surface of the knee-joint in an adult female, but is too small for an adult male which is about 90 pounds. In the Elephant and Megatherium, the pressure of the air upon the joints is greater in proportion to the increased bulk and weight of their limbs. In the latter the area of the plane bounded by the edge of the cotyloid cavity, is an ellipse whose diameters are seven and eight inches, and therefore present a plane surface exceeding 43.9824 square inches, which, being multiplied by fifteen, with the barometer at 30 inches, will be $= 43.9824 \times 15$, or about six hundred and sixty pounds pressure upon the cotyloid joint of this greatest of terrestrial Mammalia.

Muscles.—The amount and effects of muscular contraction, the absolute and relative power of muscles in reference to their length, mass, and obliquity of direction, and the expenditure of their power to support given weights, will now be either simply noticed or briefly estimated.

In the application of muscles to the purposes of locomotion we find them so arranged as to produce great velocity, and at the same time to admit a great extent of motion, still preserving the beauty of proportion. These objects are obtained, 1st, from the oblique directions of their fibres towards the tendons; 2d, from the obliquity of the direction of the tendon to the bones on which they act; 3d, from the proximity of their points of insertion to the articulations of the bones, or axes of motion in the joints.

The muscles are capable of contracting (according to the researches of MM. Prevost and Dumas) about $\frac{23}{100}$ or nearly one-fourth their whole length, which, owing to the circumstances just mentioned, is sufficient to produce all the positions and motions observed in animals.

It has been already determined by experiment that the volumes of muscles do not alter by contraction, their thickness only increasing as they decrease in length, and *vice versa*.

The comparative power of muscles in the same animal, according to Borelli, may be thus estimated:—

When two muscles are composed of an equal number of fibres, or are of equal thickness but of unequal lengths, they will suspend equal weights, but their motor powers and the height to which they are capable of raising the weights will be as the lengths of the muscles.

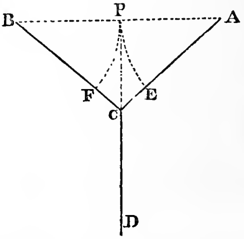
2d. When the lengths of the muscles are equal and their thicknesses unequal, their relative powers will depend upon their thicknesses, but they will raise weights to equal heights.

3d. When the lengths and thicknesses are unequal, the weights they will raise will depend on their thicknesses, and the heights to which they will raise them will be as their lengths.

When the fleshy fibres of a muscle lie parallel to the tendon, the space through which they will draw it equals the contraction of the fleshy fibres; but when they are inserted obliquely into the tendon, the space through which they will draw it will vary with the inclination.

Thus, let two equal fleshy fibres, A C, B C, (*fig.* 218) similarly situated with respect to the tendon C D, be inserted obliquely at C, join A B, and produce D C to meet it in P, then D P is perpendicular to A B. Now if the points at A B be considered as fixed, and the angle A C P be such that radius : its sine : : A C : to the length of A C when contracted, then the joint action of the fibres will draw the point C to P.

Fig. 218.



For with A B, as centres describe the circular arcs P E, P F, touching each other at P, then it is evident that the point C will, after the contraction of C A, be somewhere in the arc E P, because the radius of E P is the length of A C when contracted; for a similar reason C will be somewhere in F P; therefore it will be at P, their point of contact. The same result becomes apparent from the consideration that the forces in the direction C A, C B are equivalent to forces in the direction C P, P A and C P, P B respectively, of which the forces in the direction C P are not counteracted, but gradually diminish and become zero when the fibres are at right angles to their tendon, that is, when C coincides with P. It is here assumed that there is no obstacle to the free motion of the tendon in the line C P.

If the obliquity of the fibres be *less* than A C P, the arcs will intersect in some point between P and C, and the contractile force will be insufficient to draw C to P. If, on the contrary, the obliquity be *greater* than the angle A C P, the arcs will not meet, but C will be drawn to P. In this case the contractile force is more than sufficient for the object to be attained. All other things remaining the same, the space C P will be greatest when the obliquity is that which is stated in the proposition. If $A P = \frac{3}{4} A C$, the ∠ A C P is 48° 35′ nearly.

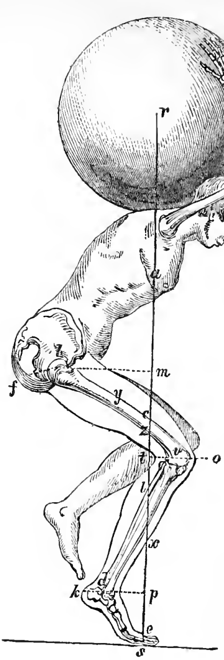
From the researches of the Professors Weber we learn that the weight of the extensor muscles generally predominates over that of the flexors; those of the leg being selected, their proportions in two well-formed healthy subjects were found to be as $\left(2403.2 + \frac{1021.1}{2}\right) : 810.3 + \frac{1021.1}{2} = 2913.75 : 1320.85$,* or as 11 to 5 in favour of the extensors, the proportions are divided by 2, or halved, to allow for the double office which some muscles perform of both flexion and extension, according as either end becomes the fixed point. The preponderance of the weight of the extensors becomes greater if the double action of each be omitted in the computation and the whole weight of each set be substituted; the proportion then becomes, 2403.2 : 810.3, or as 3 to 1 nearly.

The weight of the extensor muscles, when compared with that of the rest of the leg, is in the proportion of 5 to 9, and to the whole of the muscles, including the flexors, as 3 to 4, consequently the extensor muscles of the leg weigh three-fourths of the whole series.

Borelli has given approximate values for the powers of a great number of the muscles of the human body, from which we select a few computations which will convey an idea of the enormous amount of their absolute power and the large proportion of it which is sacrificed in order to gain velocity. Borelli states that the whole force expended by the muscles of the arms, when stretched horizontally, is 209 times greater than that of any weight suspended at its extremity, and that the force of the biceps to that of the brachialis is as 3 to 2.6, or as 15 to 13, and their absolute forces as 300 to 260. He estimates the force of the deltoid at 61600 pounds, the sum of the forces of the intercostal muscles at 32040 pounds, and of the glutæi at 375420 pounds. The extensor muscles of the hip, knee, and ankle-joints have also a large proportion of their power sacrificed to velocity; the amount of this interchange has been estimated upon the following principles of Borelli.

Let us suppose a porter carrying a weight to be in the act of stooping in order to enter a doorway with his load; his body is bent, with one leg raised from the ground, and the heel of the

Fig. 219.



other elevated, as in *fig.* 219; he is sustained in this position by the glutei (*f*), the quadratus femoris (*y*), and the gastrocnemius and soleus (*l*). Then if the weight $r = 120$lb., the weight of the porter 150lb., the line $r\ s$ be the direction of the force of gravity cutting the femur and tibia in c and x, the centre of gravity of the man be at b, and the common centre of gravity of the man and his load be at a, then the weight of the man from the head to b will be $= \frac{150}{2}$lb. $= 75$lb., and of the section b to c, by supposition, is $= 47$, therefore the weight of the arc $a\ b\ c = 75 + 47 = 122$, also by supposition the section $c\ v\ x = 20$, and consequently the whole arc $a\ b\ v\ x = 142$, also the distances of the directions of the muscles from the axes of the joints to the distances of the line of gravity are, according to Borelli, in the following ratio: $\frac{1}{2}$ the distance $f\ b$ is to the distance $m\ b$ as 1 is to 8; $\frac{1}{2}\ o\ v$ is to $t\ v$ as 1 to 6; $\frac{1}{2}\ k\ d$ is to $p\ d$ as 1 to 3; and $t\ v$ to $b\ m$ as 3 to 4; hence we derive these proportions:—

$$t\ v : b\ m :: r + a\ b\ v\ x : z,$$

or $3 : 4 :: 120 + 122 : 322\frac{2}{3}$lb. = the pressure of the weight of man and load at the point z.

$$a\ p : b\ m :: r + a\ b\ v\ d\ f : s,$$

or $3 : 8 :: 120 + 150 : 720$ = the force of the whole weight at s.

$$\tfrac{1}{2}\ b\ f : m\ b :: r + a\ b\ c : g,$$

* 2403.2 = the weight of the muscles in grammes† acting over one joint of the leg, viz. the glutæi = 936.0, vasti and cruralis = 1092.0, soleus = 375.2, and 1021.1 = the weight of those flexors and extensors of the leg acting over two joints, viz the rectus = 199.2, semitendinosus = 128.2, semimembranosus = 206.5, biceps = 129, gastrocnemius 358.

† A grain = 0.067508 gramme.

or $1 : 8 :: 120 + 122 : 1936 :=$ the force resisted or employed by the glutei muscles.

$$\tfrac{1}{2} v o : t v :: z : y,$$

or $1 : 6 :: 2322\tfrac{2}{3} : 1936 :=$* the power exerted by the quadratus femoris;

$$\tfrac{1}{2} k d : d p :: s : l,^*$$

or $1 : 3 :: 720 : 2160$. The last proportion gives the force exerted by the gastrocnemius and soleus muscles to sustain the weight of the man together with the weight r; now as the sum of the forces exerted by the muscles $f + y + l = 2 \times (1936) + 2160 = 6032$, and the weight supported being only 120lbs., it follows that the extensor muscles of the leg, to sustain this weight, exert a force = 6032lbs., being more than fifty times the weight.

Force of muscles at various stages of their contraction.—The variations which the force of muscles undergoes in different states of their contraction have not yet been thoroughly investigated; though it is a subject not only susceptible of being pretty accurately determined, but also leads us to form a more correct hypothesis of the laws which regulate the contraction of the muscular fibres, and of the physical operation of the vital agents which are the immediate causes of the contraction.

The force of muscles, according to the experiments of Schwann, increases with their length, and *vice versâ*. His experiments were made on the gastrocnemius muscle of a frog. The apparatus which he employed consisted of a board, to which the frog was fixed, with the thigh in the horizontal position, the leg being raised so as to be perpendicular to the board, and the foot again flexed to the horizontal position, in which posture the limb was firmly fixed; a rod or beam was suspended over the board and made capable of turning upon it as its axis of oscillation. This balance beam was unequally divided with respect to its axis of motion, one arm being to the other as 1 to 6. To the longest arm of the beam a scale was separated; to the other arm the tendo Achillis (which had been carefully exposed and detached from the heel) was attached by means of a thread; by this method a very small contraction of the muscle caused the other end of the beam to revolve through a much greater space, so that the slightest contraction of the muscle became very apparent. The ischiatic nerve was then laid bare, cut through high up in the thigh, and drawn out, great care being taken not to injure the surrounding vessels. The nerve was then laid upon two wires, connected with a galvanic battery, consisting of a single pair of plates, one of the wires being connected with one pole of the battery, and the other made to communicate with the opposite pole by using a slight pressure upon it. The skin was left entire, except where the tendon and nerve were exposed. By this simple apparatus, Schwann observed that the force of the muscle was at a maximum when at its greatest elongation, and at a minimum at its greatest contraction. In a series of five experiments, which were repeated at equal intervals, the forces of the muscles at different lengths were in the following proportions:—

No. of Experiments.	Force of Muscle in grains weight.	Comparative length of Muscle.	Difference in length.
1.	0	14.1	
	60	17.1	3.
	120	19.7	2 6
	180	22.6	2.11
	0 end of experiment.		
2.	0	13.5	
	100	18.8	4.3
	200	23.4	4.6
	0 end of exp. 14.4		
3.	0	13.7	
	50	18.7	4.3
	100	20.3	2.1
	50	17.7	
	0 end of exp. 14.1		
4.	0	13.5	5.6
	100	19.1	4.1
	200	23.2	
5.	100	16.8	
	0	12.17	4.1
	100	16.1	2.4
	200	18.7	
	100	16.1	
	0	11.17	

This table shows that twice the comparative length coincides with twice the force of the muscle, and that at its greatest contraction the force = 0. In the first two experiments the increase of force and length of muscle were uniform; but in the last three the ratios of the force and the length varied; the earliest experiment, however, was performed when the animal might be supposed to be nearest to its normal condition, and therefore when the result approximated most nearly to the healthy play of the muscle.

These experiments of Schwann are opposed to the hypotheses of Prevost and Dumas, as well as to those of Meissner, who regard the phenomena of muscular contraction to be due to the force of electric attraction, but as the latter increases in force the more nearly the attracted bodies approach each other, and decreases as they recede in the inverse ratio of the square of the distance, and as the force of elastic bodies varies in a ratio differing from that of muscles, when their length and force affecting them vary, we conclude that the contraction of muscles does not depend upon any of the known laws connected either with electrodynamics or the forces regulating the molecules of elastic matter.

If we conclude from the experiments of Bergolotti, Mayo, and Prevost and Dumas, that the contraction of muscles is unaccompanied by a diminution of bulk, and that the aggregate molecules present equal volumes and are at equal distances from each other, whether contracted or not, the electric force would remain constant, whilst the muscular force varied; or if with Professors Gruithuisen and

* This computation differs from that in the 53d prop. of Borelli, where he has substituted new and arbitrary values for s and z in the two last proportions, which diminish the values of y and l.

Ermann, that the molecules approximate during contraction, the magnetic force would increase at the same time, and the muscular force is observed to decrease, therefore both of these hypotheses are inconsistent with the theory of the identity of the magnetic and muscular forces.

The power of muscles, however, rapidly decreases by exertion, especially in some of the lower animals, such as the Ophidian and Batrachian reptiles; the ratio of decrease is in proportion to the energy of action, until, by continued exertion, locomotion becomes impossible. It has now been sufficiently demonstrated that muscles are capable not only of moving the levers on which they act with great force and velocity, and of prolonging their action for a greater or less period, but that they are endowed also with a surplus of force beyond what is necessary for locomotion, and which is applied to the various purposes of life.

Having now given a brief statement of the mechanical principles applicable to the locomotion of animals, we shall proceed to give an outline of their various modes of progression according as it is performed in *air*, in *water*, or on *solids;* and in the first place, for example, we shall select those that move by means of an aeriform medium.

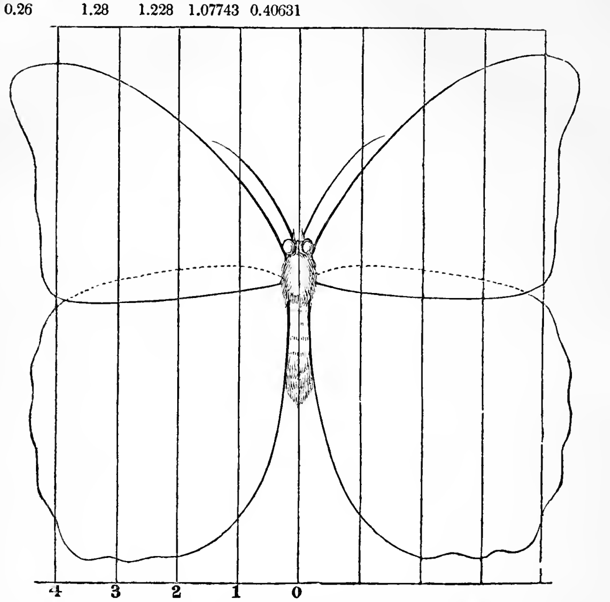
Sect. II. *Flying.*—Flying depends on the power which animals possess of raising themselves in the air, and of moving through it with considerable velocity in every direction. The power of flight is denied to a large proportion of the animal kingdom, and requires for its exercise a certain configuration of body, adjustment of parts, and modification of structure, based on the most profound principles of dynamics. In flying, as in swimming, the animal moves in a medium which furnishes a suitable fulcrum to its levers or locomotive organs, whatever may be their kind or form. Air supplies the medium to animals that fly as water to those that swim. Air, however, being more than eight hundred times lighter than water, gives a proportionably diminished support to the animals which move in it; consequently, instead of having the whole or nearly the whole weight of the body sustained, as when plunged in water, the same animal weighs as much more in air as corresponds to the difference in the specific gravities of the two fluids, or nearly as $1\frac{2}{9}$ to 1000. The weight of the volume of air displaced by the equal volume of any insect or bird indicates the amount of buoyancy or force acting vertically upwards, in opposition to the force of gravity on the mass of the body of the animal acting vertically downwards. The difference between the specific gravity of animals and that of the atmosphere represents the weight necessary to be overcome in flying by the action of their locomotive organs; or, in other words, whatever may be the amount of the force of gravity on the mass of particles composing the whole animal in a direction vertically downwards, and the resistance of the air on its surface due to its velocity, an equal force acting vertically upwards will be required to sustain it in the air, and a still greater force to cause it to rise. It is the vast preponderance of the weight of most animals over that of the air they displace, which constitutes the chief obstacle to their flight, in addition to their inappropriate form and the unsuitable organization of their locomotive organs.

Flight of insects.—The flight of insects depends on the same principles as that of birds, notwithstanding the dissimilar structure of their bodies and wings. The skeleton of insects is both light and dense, and, without greatly adding to their weight, affords the necessary fulcrum for the action of an elaborate muscular system. The mobility of the segments of the abdomen upon the thorax enables the insect to bend upon itself, and to adjust the position of the centre of gravity, with respect to the articulation of the wings during flight. The attachment of the wings to the trunk lies above the centres of magnitude and gravity, so that the insect is kept steady whilst flying. Compared with their volume, the weight of insects is less than that of birds: the lightness of their skeletons and the diffusion through their bodies of tracheæ and air cavities, greatly tend to diminish their specific gravity and the quantity of muscular action employed during their flight. The form of their bodies is very irregular, but being for the most part either cylindrical or ellipsoidal, is well adapted to pass through the air with little resistance.

In the Diptera, the single pair of wings is articulated to the meso-thorax; in the other orders with two pairs of wings, the first pair is also articulated to the meso-thorax, and the second to the meta-thorax. The wings are composed of a duplicature of the common integuments continued from those parts of the body. In the Diptera and Hymenoptera the ratio of the areas of the wings to their weight is much less than in the Lepidoptera; and as this ratio decreases, the number of the vibrations of the wings in a given time proportionally increases. Hence it is vastly greater in the two former orders than in the latter. The neuræ when injected with air and fluid assist in giving expansion and tension to the wings; an office compared by Jurine to the support given to a sail by its cordage. Insects are capable of varying the area of their wings during their elevation and depression, by alternately filling and exhausting the tubes, which movements follow synchronously the expansion and contraction of the thorax. The muscles which act indirectly on the wings at the same time effect changes in their surfaces, angular inclinations, and ratios of velocity during their ascent and descent. There is an elaborate mechanism provided in the structure of insects relating to their flight. The surfaces of their wings, like those of birds, are in general slightly convex above and concave below. In the Strepsiptera, Orthoptera, and Hemiptera their figure approaches that of the quadrant of a circle. In the Diptera, Coleoptera, and diurnal Sphinges it is ellipsoidal. The figure of the wings varies, how-

Fig. 220.

Areas of wings within the parallels, showing the ratio of increase with their distances from the axis of the body.



Distances of parallels from the axis of the body in 0.4 of an inch. (*Morpho automedon.*)

ever, considerably in different orders of insects, and they are here described rather in the language of geometry than in that of entomology. The ratio of the area of the wings to the weight of the insect varies in each order, and approximates to a constant quantity only in the same order. The wings of insects diminish in thickness from their base to their apex, and from their anterior to their posterior margin;* the strongest nervures traverse the anterior margin of the wing, and confer on that portion the greatest resisting power. The posterior margin being weaker is inclined upwards and backwards in reference to the direction of its stroke. The plane of the wing, as Straus has correctly remarked, is therefore inclined at a different angle to the horizon at every moment of its descent. By the composition of forces the obliquity of the wings backwards and downwards gives to the centre of gravity an impulse upwards and forwards. The radial and cubital nervures in insects supply the place of the bones of the arm in birds; and though different in structure, they have the same mechanical effect. The anterior nervures being articulated to the apophyses of the wings, and being fixed at their extremities upon the two axillary first pieces, the latter, with the wings, form a *lever of the first order*, and when the internal borders of the two axillary pieces are lowered the wings are raised, and vice versâ; or as the axillaries are articulated upon the border of the clypeus, the movements of elevation and depression in these produce the contrary movements in the wings.* The wings of insects oscillate during flight through arcs of various lengths, which depend on the distances of the centres of the wings from their axes of motion, and other dynamic conditions. In the Lepidoptera they appear to describe an arc of 180°, so as to meet each other at each elevation and depression. In some other orders the arc of oscillation appears to be much less. Amongst the Coleoptera, in some of which the elytra assist the under wing in flight, according to Chabrier, the latter describe an arc four times as great as the former.† In estimating the number of

* See Chabrier sur le vole des insects, c. i. p. 424.

* See Straus-Dürckheim, loco cit. 212.

† Dans les hannetons chaque aile, en volant paroît décrire un arc de plus de 200° cent, tandis que celui tracé dans le même temps par les élytres est peut-être au dessous de 50° cent. See Chabrier, sur le vole des insects, p. 31.

strokes made by the wings of insects as well as of birds during flight, it is necessary to take into the account the length of the arc in which they oscillate.

The oscillations of the wings of insects are too rapid to be numbered by common observation. The principles of optics,* acoustics, and dynamics have been employed to determine them during their flight. According to Burmeister the pitch of the sound made during flight varies with the number of strokes made by the wings, although the production of the sound is perfectly independent of them.† If the number of strokes is synchronous with the number of vibrations which produce the sound, we can ascertain the number of their oscillations very readily; but we are not yet furnished with sufficient evidence that each stroke of the wing is coincident with one musical semi-vibration to determine this question with precision. According to the analysis made on the flight of birds, if the same data may be considered applicable, we shall see by Chabrier's investigations when all other things remain the same, that the number of strokes made by the wings of insects will vary as the square roots of the weight directly, and of the area of the wings inversely.

In the Coleoptera, the ratio of the area of the wings to the weight of the insect is small in comparison with other orders. The elytra of the Coleoptera add to their weight and surface in passing through the air, without contributing either to the vertical elevation or horizontal velocity of the insect; on the contrary, as their surfaces are inclined to the axis of the body and the direction of motion, they retard the velocity of the beetle in moving against the wind. The centre of the forces lies posterior to the articulation of the wings, and as the angle of inclination of the elytra tends to elevate the head and depress the abdomen by its resistance to the wind, the axis of the body becomes inclined vertically during flight. In a stag beetle weighing forty grains, the area of each elytra measured 0.366364 of a square inch, and the true wings, calculated as the quarter of an ellipse, gave 0.6263565 of a square inch each, or 1.2527126 in. for both. The same measured by a graduated scale gave 0.62240 in. each, which shows how nearly the form of the true wings approaches to a segment of perfect ellipse. Those Coleoptera in which the ratio of the surface of the wings is very small cannot fly against a strong wind. Olivier says, " None of this class can fly in opposition to the wind," but this assertion is opposed by Kirby, who states that the Melolonthæ Hopliæ fly in all directions; others, as the Cicindelæ, take short flights, and may be easily marked down by the entomologist. The Cetoniæ expand their wings in flight without elevating their elytra, as is done by other Coleoptera.

The *Dermaptera*, though generally on their legs, take flight towards evening. The wings of the earwigs are ample; the nervures radiate from a common centre to the external margin of the wings, which they expand like a fan. According to Ray, the tegmina of the Orthoptera assist the wings in flight.* The Grillus domesticus flies with an undulatory motion like the woodpecker, alternately making a few strokes with the wings in order to give a projectile velocity to the body upwards, and then folding the wings to descend on the opposite side of the vertex of a parabolic curve. Owing to the analogous structure of their wings, the Gryllus campestris and Gryllotalpa are capable of using them in a similar manner. The Hemiptera employ their hemi-elytra to assist the wings in flying.* By this means the area of the wing is increased, a greater surface is given to it for striking the air, the ratio of the surface of the wings to the weight of the body is augmented, the quantity of action and the number of vibrations necessary to sustain it in the air is diminished, and the power of flight is consequently increased.

The *Lepidoptera* are furnished with a far greater area of wing in proportion to the weight of their bodies than is observed in any other flying animal. The under wing approaches in figure to the quadrant of a circle, and in many species the two meet posteriorly and form a semicircle. The anterior and under wings are locked together during their descent so as to give them a synchronous action, and a compact surface to resist the air. The surfaces of the two wings on each side increase with the distances of their sections from the axes of motion; in the Morpho automedon (*fig.* 220), in which the areas of the sections of the wings lying between the parallels 1, 2, 3, 4, drawn at equal distances from the axis of the body, will be seen to increase (the last one excepted) as the distances from the centre of motion of the wings increase; the effect of which is, to throw the centre of resistance to a greater distance from the axis of motion, so that the muscles of the wing act at a mechanical disadvantage; and the weight of the body being small in proportion to the area of the wing, the body oscillates considerably at each elevation and depression, and its flight is rendered unsteady.

The surface of the anterior wing is less than that of the posterior, being as 2.08 : 2.4483471 square inches, and the sum of the surfaces of the four wings is =9.0566942 inches. As the solid contents of the body are very small when compared to the surface of the wings, we naturally conclude that the Morpho has prolonged powers of suspension. The great magnitude of the wings of the Lepidoptera are generally in proportion to the weight of their bodies, and the force of their muscular system endows them with great powers of flight; but it is most frequently accomplished in a zig-zag path. In the Pontia brassicæ the weight of the insect is found to be 1.525 gr.; the area of the anterior wing 0 6 square inch, the area

* See Nicholson's Journal, 4to. vol. iii. p. 38.

† Remarks on the causes of sound produced by insects in flying, by Dr. H. Burmeister. Taylor's Scientific Memoirs, vol. i. p. 378, 1837.

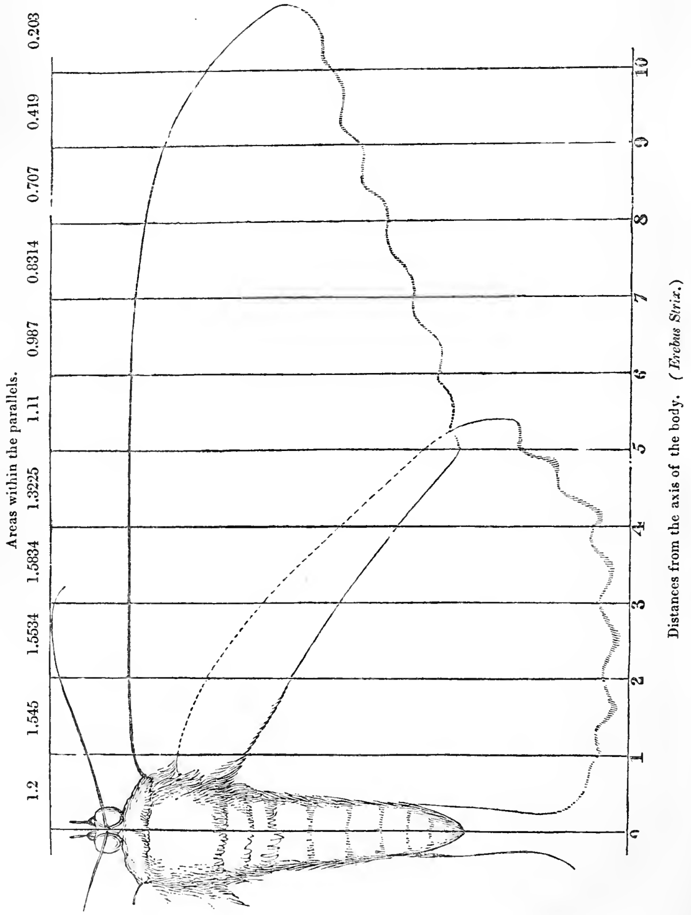
of the under wing 0.65; the sum of the areas of the two wings consequently is =1.25; but when placed in the position of flight, as the anterior wing lies partially over the under wing, the whole effective surface of the two wings measures 0.83, and that of the four 1.66 in. During repose the dorsal planes of the wings of the diurnal Lepidoptera are directed vertically and brought into contact.

Nocturnal Lepidoptera.—Many of this order have large organs of flight; their wings, which in repose lie in or beneath the horizontal plane, are triangular, their apices being the most distant points from the body when the wings are extended, and their areas are in the inverse ratio of their velocities, and their distances from the centre of gravity. Thus in the Erebus Strix (*fig.* 221) the wings are greatly expanded and of a form the best calculated for rapid flight, the areas of the sections of the wing being, for the most part, in the inverse ratio of their distances from the axis of motion; consequently the reverse of that of the Pontia, the Morpho, and most of the diurnal Lepidoptera. The anterior wing is much larger than the posterior, being as 7.175 to 5.095 square inches. The area of the four wings is therefore about 12.270 inches, which, being very considerable in proportion

Fig. 221.



to the cubic contents of the body, endows this insect with great powers of suspension in the air and with great velocity of motion. The triangular figure of the wings prevents the unsteady undulating progression observed in the diurnal Lepidoptera, and the flight is consequently more direct as well as more rapid. The wings of many of the moths are of considerable dimensions. The largest male Atlas moth in the collection at the British Museum measures 5½ inches on each side, estimated from their axes of motion to the apices of the wings, presenting a total area of 26½ square inches. If the force of the muscles acting on the wings is proportional to their areas, they must possess the most extensive power of flight. The Bombyx mori, or silk-worm moth, is stated to travel more than a hundred miles a day.*

The *Neuroptera* have a separate set of muscles appropriated to the movements of each wing, which being detached can be moved either synchronously or independently of each other: the muscles also are actually inserted into the wing, instead of moving them indirectly, as in other orders of insects. The surfaces of the four wings of the Libellulæ, or dragon-flies, are nearly equal in most species; they are always expanded in repose, and extended horizontally at right angles to the axis of the body, so that they take flight in an instant. Their figure is lanceolated. The ratio of the united areas of the four wings to the weight of the body is greater than in the Coleoptera and Hymenoptera, and the muscular power is proportionally augmented. The articulation of the wings being situated above the centre of gravity keeps them steady in flight: their velocity is very great, exceeding that of the Swallow. Leeuwenhoek once observed one of this tribe in a menagerie 200 feet long, chased by a swallow; the insect flew with such velocity, and turned to the right and left in all directions so instantaneously, that the swallow, with all its powers of flight and tact in chasing insects, was unable to capture it, the insect always keeping about six feet in advance of the bird. The great length and surface of the wings of the Libellulæ, and the power of the muscles acting on them, is such that they appear to be never tired of flying in quest of their prey.

In a specimen of the Æshna maculatissima, which weighed fourteen grains, the area of the anterior wing was 0.7324 in. the posterior 0.8988 in. and the area of the four wings 3.26408 square inches. The preponderance of surface in the posterior wing enables the Libellulæ to change the direction of their path of motion with great facility, and to capture their prey on the wing. Previously to taking flight, this Æshna exerts a vibratory movement with its wings; the oscillations are made in very minute arcs, and with great rapidity, producing a faint though distinct sound. The pitch indicates that the wings perform ninety-six vibrations in a second. On taking flight the wings oscillate through larger arcs, with a less number of vibrations, the amount of which it is not easy to determine, and does not depend, as some distinguished entomologists have supposed, on their mutual friction.

In a Triphæna pronuba, weighing 8.545 grains, the area of the anterior wings measured 0.6213, and that of the under wings 0.68 square inches, making the sum of the areas of the four wings 2.6026 square inches.

In the *Hymenoptera* the ratio of the areas of the four wings to the weight of the insect is less than in the Neuroptera, and they are consequently obliged to make a greater number of strokes in the same interval of time in order to suspend themselves in the air. The areas of the upper are greater than those of the under wings. When expanded they are retained in the same place, and are linked together by means of small hooks, so that the upper and under wings act simultaneously and with greater power. A humble bee, which weighed 6.2 grains, had wings the sum of whose areas measured 0.366 of a square inch, or rather more than $\frac{1}{20}$th of a square inch to each grain weight of the body. Bees are not only celebrated for the geometry displayed in the structure of their cells, but also for the precision with which they return to their homes by the shortest path or in a straight line. The collectors of honey make use of this fact to discover their nests. Having captured two of these insects, they separate them some yards from each other, and on setting them free, ascertain with an instrument the angles respectively made by the lines of their flight with that between the points of their departure, then the point where the two lines of direction intersect each other indicates the position of the nest. The humble bee, wasp, and hornet fly with great force, but owing to the weight of their bodies, compared with the areas of their wings, cannot fly with much speed against a strong wind, so that a person might easily outstrip them by running in the same direction against the wind. When disturbed, or before leaving their abode, they wheel round the spot in a large circle, and then fly off at a tangent to some part of the curve. The Ichneumons are provided with a far greater expansion of wing, in proportion to their weight, than the Bees, and can consequently sustain themselves in the air with less expenditure of muscular action. In a species of ichneumon allied to Ophion luteus, which weighed 0.5 gr. the areas of the anterior wing measured 0.0832 in. the posterior 0.0480 in. the sum of the two wings = 0.1322 in. and that of the four = 0.2644 in.

The *Diptera* are furnished with only two wings, which when in repose lie directed obliquely backwards upon the abdomen; their figure is nearly that of an ellipse, and their areas are ample when compared to the weight of their bodies. Three examples of *Muscæ vomitoriæ* for instance were found to weigh 2.4375 grains, which gives for the mean weight of each 0.8025 gr. and the mean areas of both wings were found to be from $\frac{1}{12}$th to $\frac{1}{10}$th of a square inch. Instead of posterior wings they have poisers, the articulation of which to the thorax is placed more posteriorly than in the four-

* Lin. Trans. vol. iii. p. 40.

winged insects, so as to lie above the centre of gravity. According to Dr. Derham, if either a poiser or winglet be cut off, the insect flies as if one side overbalanced the other, till it falls to the ground; and if both be removed, it flies unsteadily. Shelver states that the removal of either winglets or poisers deprived the insect of the power of flight altogether. The pneumatic pressure which retains them inverted to the ceilings of rooms, gives them a position favourable for flying off instantaneously, the centre of gravity being below the articulation of the wings, enabling them to regain the pendant position of the trunk in flight.

In the crane fly the centre of gravity is adjusted, and the direction of flight directed by its long legs; the two fore legs being extended forwards, and the four hind legs backwards. According to Kirby, the one represents the prow, the other the stern of a ship. The velocity of the house, and large flesh flies (Muscæ domestica et vomitoria) appears to be from five to six feet in a second, or about four miles in an hour; but if favoured by the wind, they are seen flying round the ears of horses when travelling at the rate of from ten to twelve miles in an hour.*

The following table presents at one view the proportions of the areas of the wings in square inches to their weight in grains of various species of insects which have been already described in the text.

Order.	*Species.*	*Area of Wings in square Inches.*	*Weight of Body in Grains.*
Coleoptera	Lucanus cervus	1.2527126	40.
Hymenoptera	Bombus	0.366	6.2.
	Ophion luteus	0.2644	0.5.
Diptera	Musca vomitoria	0.083333 or $\frac{1}{12}$	0.8025.
Lepidoptera	Pontia brassicæ	2.50	1.525.
	Triphæna pronuba	2.6026	8.545.
Neuroptera	Æshna maculatissima	3.26408	14.

By the help of this table we are enabled to compare the proportions of the area of the wing to the weight of the insect in different orders, and to estimate the relation between these proportions and the absolute powers of flight, when the latter have been ascertained by experiment.

If the velocity and power of suspension varied in insects precisely in the same ratio as the areas of the wings to the weight of their bodies, we should be enabled to compare with tolerable accuracy the relative powers of the flight of insects from data similar to the preceding, but there are several other mechanical and physiological conditions involved; such as the ratio of the force of the muscles to the areas of the wings, and the figure and structure of the latter. The Lepidoptera which have the greatest surface of wing in proportion to their weight, should surpass all other insects in power of flight, yet the diurnal section at least yield to the Libellulæ in velocity, if not in the duration of their suspension in the air. From the preceding data we conclude, that to render a man, whose weight is 150 pounds, capable of suspending himself in the air by the assistance of artificial wings, with the same facility as insects, would require an extent of surface beyond the control of his muscular force, and consequently that the act is impossible.

Flight of Birds.—In the organization of birds, we observe that many parts common to other animals are modified, the power of the muscular system is increased, and new forms of matter are introduced to confer on them the power of flight. The bulk of birds is less than that of quadrupeds of equal strength, and owing to many of their bones being permeated with air, and their skin clothed with feathers, their specific gravity, and consequently the demand on their muscular power are diminished.† Instead of the cylindrical form observed in animals which move exclusively on solids, the anterior extremity of birds is expanded into a triangular surface, of which the apex is the distal, and the base is the proximal section of the wing in reference to the axis of rotation. The arm is articulated to the trunk by a ball and socket joint, permitting all the freedom of motion necessary for flight, whilst in consequence of the axes of motion in the gynglimoid joints of the fore-arm being directed either perpendicularly or obliquely to the ascent and descent of the wing, it is prevented from yielding to the resistance of the air during elevation and depression, and is more conveniently folded on itself during repose. The surface of the wings may be increased or diminished by abduction and adduction, in consequence of which the resistance of the air to their motion may be proportionally varied in the up and down strokes. The amount of this resistance is also varied by the surface of the wing being convex above, and concave below. The feathers are moreover provided with a curious mechanism by which the barbules lock into each other, so as to unite all the parts of the vane, and present a continuous surface to the air. The ten primary and the secondary feathers, which have the greatest leverage, are inserted into the arm and fore-arm, and directed so as to produce the greatest surface of wing

* See Kirby and Spence, vol. ii. p. 357.

† 1. The Pelicanus onocrotalus is five feet in length, but its skeleton weighs only twenty-three ounces, whilst the whole animal weighs twenty-five pounds. See Roget's Bridg. Treat. vol. i. p. 490.

2. The skeleton of the Carrion Crow when dry weighs only twenty-three grains. Jaquamin, An. Sci. Nat. series 2, 11, p. 2718.

3. Many entire Humming Birds weigh only one-eighth of an ounce, or one drachm.

without very sensibly increasing its weight. The scapulars which have the least velocity are shorter and weaker. The length and strength of those feathers which contribute so largely to increase the area, vary directly with the velocities of that portion of the wing to which they belong. The ratio of the area of the wings of birds to their weight is by no means constant. It is least in the Cursores, such as the Ostrich, Cassiowary, and Emeu; greater in the Insessores, as the Raven, Crow, and Humming-bird; and greatest in the diurnal Raptores, as the Eagle, Falcons, and Vultures. The power of flight in birds, provided the muscular forces vary in proportion, is as the areas of their wings directly, and as their specific gravities inversely. Owing to the triangular figure of the expanded wing, the area of its sections diminishes as their distance from the centre of gravity increases, and from the same cause the areas are in the inverse ratio of the velocities corresponding to the distances of the sections from the axis of motion. The centre of resistance coincides very nearly with the middle of the length of the wing from the shoulder-joint to the tip. The wing is moved on the principle of the third order of levers, and the power is applied sufficiently near the axis of motion to produce a considerable relative velocity. The power of the muscles acting on the wing is increased in proportion to their mass, being to those of the inferior extremity (according to Borelli) in the proportion of more than three to one, their absolute power in proportion to the weight of the bird being as 10·000 to 1. In order to give the osseous framework the surface and strength necessary for the attachment of the great pectoral muscles which act on the wing, the sternum is carinated, whereby its surface is increased in proportion to the mass of the muscular fibres which are inserted into it, and the shoulder-joints are strengthened by the elongation of the coracoid processes, and the magnitude of the clavicles. The fixed condition of the ribs and vertebral column tends also to strengthen the thoracic sections of the bird, and enables it to resist the enormous muscular force applied to it during flight.* This brief outline of the manifold adaptations necessary for aerial progression will give some idea of the number and complication of the elements which enter into the composition of so small a fabric, and of the enormous muscular power with which birds are endowed, compared with their bulk and weight. When a bird rises from the ground, and at the moment it begins its flight, the first impulse is communicated to its centre of gravity by the sudden extension of the legs, as in leaping. During this action the humerus is raised; the wings are unfolded and spread out horizontally by the extension of the fore-arm, and of the carpal, metacarpal, and phalangeal bones. The force resulting from the sudden extension of the legs elevates the whole mass of the bird above the plane of position, and the body thus raised being deprived of the support previously afforded would begin again to fall by its own weight, as soon as the projectile force became insufficient to sustain it, but the wings having in the meantime been spread out to their fullest extent, are made to descend with great velocity by the contraction of the powerful pectoral muscles. In consequence of the planes of the wings being disposed either perpendicularly, or obliquely backwards to the direction of their motion, a corresponding impulse is given to the centre of gravity. The resistance of the air to the wings during their depression through a greater or less arc of a circle becomes greater than the force of gravity on the mass of the bird, together with the resistance of the air on its body due to its velocity, and consequently the bird rises. During the ascent of the wing, the opposite effect takes place. The bird has not only to encounter the resistance which the air opposes to the motion of the wing during its back stroke, but also the resistance due to its figure when in motion, as well as the force of gravity. These are so many forces tending to neutralize the down stroke of the wing, and to produce an opposite effect, so that there will result a motion, the amount of which may be pretty nearly ascertained when the necessary data are obtained by experiment.

The principal data required for computing the quantity of muscular action expended, the velocity of the centre of the wing, and the number of its periodic oscillations necessary to sustain the bird in the air, may here be briefly stated. 1st. The area of the horizontal section of the body of the bird. 2d. The area of the two wings whilst they are lowered. 3rd. The area of the wings whilst they are raised. 4th. The velocity with which the bird is driven through the air. 5th. The velocity with which the wings are lowered. 6th. The velocity with which the wings are raised. 7th. The respective durations of the elevation and depression of the wings. 8th. The weight of the whole bird. 9th. The weight of an equal volume of air. 10th. The resistance of the air due to the figure and velocity of the bird. 11th The ratio of the resistance which the air opposes to the wings during their elevation and depression. 12th. The ratio of the resistance of the air to the time of an elevation of the wings to that of a depression.

These are the principal data which are deemed necessary for estimating by dynamics the amount of the force employed by birds during their flight.† If the area of the wings of birds always preserved the same ratio to their weight, the

* The position of the scapulo-humeral joint with respect to that of the great pectoral muscles throws the centres of gravity and figure below the axis of articulation of the wings, so that the animal is kept steady in flight, whilst its figure is such as to enable it to glide through the air with the least possible resistance.

† Let us suppose the bird to endeavour to rise perpendicularly in the air by equal flappings of its wings in a vertical direction, and let s = the area of the transvere section of the bird, A = the area of the wings whilst they are depressed, A' = the area of the wings whilst they are elevated, u = the velocity with which the bird rises in the air, V = the velocity with which it depresses its

velocity of the centre of the wing would be the same in all birds, and if the arc of vibration and the ratio of the time of ascent to that of descent in the wing were constant, the number of flappings would vary inversely as the distance of the centre of the wing from the axis of

wings, V' = the velocity with which it elevates its wings,* t = the time reckoned from the moment when the wings begin to be depressed, τ = the time of a depression, τ' = the time of an elevation, W = the weight of the bird, π = the weight of a cubical foot of air, g = the velocity acquired by gravity in an unit of time, k = a constant coefficient, by which we multiply the product $s\frac{u^2}{2g}\pi$, in order to get the expression for the resistance of the air to the rising of the bird, which is therefore $\pi k s \frac{u^2}{2g}$, K = a similar coefficient for the expression of the resistance of the air to the depression of the wings, K′ = a similar coefficient for the resistance of the air to its elevation. During the depression of the wing the bird is drawn downwards by the force W, arising from its own weight, and by the resistance of the air to its rising, namely, $\pi k s \frac{u^2}{2g}$, but it is driven upwards by the resistance which the air opposes to the motion of the wing, that is, $\pi \mathrm{K A} \frac{(V-u)^2}{2g}$, hence the equation to the motion will be

$$\frac{W}{g}\frac{du}{dt} = \pi \mathrm{K}\ \mathrm{A}\ \frac{(V-u)^2}{2g} - \pi k s \frac{u^2}{2g} - W,$$

or

$$2\,W\frac{du}{dt} = \pi \mathrm{K A}(V-u)^2 - \pi k s u^2 - 2\,W g \ldots\ldots\ldots\ldots(12)$$

These are approximative values. The motion of the wing being very quick, we may consider u to be constant during a depression, and if u_0, u_1 be the values of u, at the beginning and end of the depression, equation (12) will become

$$2\,W(u_1-u_0) = \tau\{\pi \mathrm{K A}(V-u_0)^2 - \pi k s u_0^2 - 2\,W g\}.\ \ldots\ldots\ldots\ldots(13)$$

Similarly if u_1, u_2 be the values of u at the beginning and end of an elevation, the equation for the motion will be

$$2\,W(u_2-u_1) = -\tau'\{\pi \mathrm{K'A'}(V'+u_1)^2 + \pi k s u_1^2 + 2\,W g\}.\ \ldots\ldots\ldots\ldots(14)$$

By adding the two latter equations together we have

$$2W(u_2-u_0)=\tau\{\pi \mathrm{KA}(V-u_0)^2-\pi k s u_0^2-2Wg\}-\tau'\{\pi \mathrm{K'A'}(V'+u_1)^2+\pi k s u_1^2+2Wg\}\ldots\ldots(15)$$

Since, at the end of every flapping the wings are supposed to be in the same position as they were at the beginning of it, we must have

$$V\tau = V'\tau'\ldots\ldots\ldots\ldots(16)$$

The two equations (15) and (16) express the conditions under which the bird may acquire a given motion, the nature of which is shown by the variation $u_2 - u_0$ which the velocity u undergoes in the time $\tau + \tau'$. If we suppose the motion of the bird to be uniform during each flapping $u_0 = u_1 = u_2$, and if we take the value of V' in equation (16), equation (15) will become

$$0 = \tau\tau'\pi \mathrm{K A}(V-u_0)^2 - \pi \mathrm{K'A'}(V\tau+u_0\tau')^2 - (\tau+\tau')\tau'\pi k s u_0^2 - (\tau+\tau')\tau'\, 2\,W g.\ \ldots(17)$$

In order to fly, the bird must expend a quantity of force sufficient to overcome the resistance of the air to the motion of the wings, and, considering the velocity of the bird to be constant during each movement of the wings, the quantity of force expended in a depression will be

$$\pi \mathrm{K A}\frac{(V-u_0)^2}{2g}V\tau,$$

and in an elevation

$$\pi \mathrm{K'A'}\frac{(V'+u_1)^2}{2g}V'\tau'.$$

If we now suppose $u_0 = u_1$ as before, and substitute the value of V', we shall have for the whole force expended in an unit of time

$$\frac{\pi V\tau}{2g(\tau+\tau')}\left\{\mathrm{K A}(V-u_0)^2 + \mathrm{K'A'}\left(\frac{V\tau+u_0\tau'}{\tau'}\right)^2\right\}\ldots\ldots\ldots\ldots(18)$$

Let $\tau' = p\,\tau$, and $\mathrm{K'A'} = q\,\mathrm{KA}$, equation (17) then becomes

$$0 = p(V-u_0)^2 - q(V+u_0 p)^2 - (p+p^2)\frac{k\ s}{\mathrm{KA}}u_0^2 - (p+p^2)\ \frac{2\,W g}{\pi \mathrm{K A}},$$

* V and V′ are supposed constant during the times of elevation and depression, respectively, and are referred to the centres of the wings.

motion; but according to our experiments the weight of the Pigeon is 4347.344 grains; of the Rook 4170.25; and of the Canary 229; whilst the areas of their wings are respectively 0.6198, 1.11, and 0.054 feet: hence, we see that in these instances, as probably in other

and solving it with respect to V, we have

$$V = p\frac{q+1}{p-q}u_0 + \sqrt{pq\left(\frac{p+1}{p-q}\right)^2 u_0^2 + p\frac{p+1}{p-q}\frac{\pi k s u_0^2 + 2 W g}{\pi K A}}, \quad \ldots\ldots(19)$$

and supposing the same things in (18), it will become

$$\frac{\pi K A V}{2g(p^3+p^2)}\left\{ p^2(V-u_0)^2 + q(V+pu_0)^2 \right\} \quad \ldots\ldots(20)$$

Here we may substitute for V its value found in equation (19). If the bird merely supports itself in the air without rising or falling, $u_0 = o$, and the expressions for V and the force expended in an unit of time, viz. (19) and (20) will become respectively

$$V = \sqrt{\frac{p+p^2}{p-q}\cdot\frac{2 W g}{\pi K A}}, \quad \ldots\ldots(21)$$

$$W\frac{p^2+q}{p^2-p\,q}\sqrt{\frac{p+p^2}{p-q}\cdot\frac{2 W g}{\pi K A}} \quad \ldots\ldots(22)$$

We may suppose q to be known from the figure of the bird and the power which it has of expanding the wing in a depression, and closing it during an elevation, so as to increase and diminish the surface and resistance alternately; and in order to find the least quantity of force necessary to sustain the bird, we must give to p such a value as will make the expression (22) a minimum.

All other things being the same, we see that the quantity of force expended is proportional to the $\sqrt{W^3}$, and is also inversely as the $\sqrt{\text{density of the air}}$. Let us take, as an example, the data given by M. Chabrier with respect to the Swallow. $W = 0.01526$ kil. $\pi = 1.25$ kil. $A = 0.0086$ met. car. $g = 9.80422$ met., now from experiment it is found that a plane surface very nearly equal to the surface of a swallow's wing will produce a resistance in air equal to the weight of a column of fluid, whose base is the plane and altitude between one and a half, and twice the height due to the velocity with which the plane is moving; if, therefore, we suppose the resistance of the wing to be a little more on account of the concavity of its surface, and consider the altitude just twice the height due to the velocity, K will $= 2$. It is also evident that $p > 1$ and $q < 1$, and by giving different values to q, we may obtain the corresponding values of p.

1. Let $q = \frac{1}{2}$, then when (22) is a minimum.

$p = 3.073$

$V = 8^m.18 = 26.8304$ feet.

$(22) = W\ 10^m.36 = 33.784$ feet.

2. Let $q = \frac{1}{4}$ .... $p = 1.866$.

$V = 6^m.91 = 22.6648$ feet.

$(22) = W\ 8^m.39 = 27.5192$ feet.

3. Let $q = \frac{1}{5}$ .... $p = 1.6$

$V = 6^m.81 = 20\ 3368$ feet.

$(22) = W\ 7^m.95 = 26.0660$ feet.

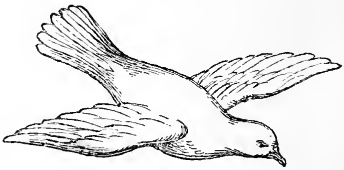
We may observe that the several values assigned to q do not produce any great variations in the values of V and (22), we may, therefore, with tolerable accuracy conclude that a bird which just supports itself in the air, expends as much force every second as would be sufficient to raise its own weight a height of 8 metres or 27.5192 feet. The mean velocity of the descending wing is about 7 metres or 22.96 feet per second, and the velocity of the ascending wing is about one-half of it. Let us now take the distance of the centre of the swallow's wing, from its axis of motion, to be three inches, and that it oscillates in an arc of $120^0 = \frac{2\pi}{3}$, then the length of this arc will be found by the following proportion $1 : 3 :: \frac{2\pi}{3} : 2\pi = 6.2832$ inches; the velocity divided by this length is $= 43.85$, being the number of arcs which would be described by the descending wing in one second, but the ascending wing takes 1.866 seconds to describe the same number of arcs, consequently this number, divided by the sum of the times taken by each wing, namely, 2.866, gives 15.3, the number of flappings, each consisting of two arcs, per second.

Such is the result by Chabrier's formula. If we apply the same formula to the case of the Pigeon, the result is 14.9, or nearly 15 flappings per second; but actual observation proves this to be nearly three times the real number; a similar discrepancy is observed in the case of the Rook, dissimilar orders, the areas of the wings do not vary as the weights of the birds.

The ratio of the times of the descent and ascent of the wing will cause a corresponding difference in the ratio of the resistance of the air, which is not as the velocity simply, but as the square of the velocity. The velocity of the wing varies according to the celerity with which the bird moves, and it moves through a greater or less arc according as the bird merely suspends itself in the air or is in rapid motion, on the rational supposition that birds employ their locomotive organs in such a manner as to economize as much as possible the expenditure of their muscular power. We find by the annexed analysis that for this purpose the ratio of the time of the descent of the wings to that of their ascent is nearly as one to two, and that the ratio of the resistance of the up to that of the down stroke lies between one-half, one-fourth, and one-fifth. In the Swallow, for example, in order that the bird may merely sustain itself in the air, the centre of the wings, according to Chabrier, must descend with a velocity of about seven metres, or 22·9662944 feet per second, which, we find by the annexed analysis, gives 15·3 for the number of vibrations, and for the minimum amount of action expended in the same time, a force which would raise its own weight to the height of 26·246 feet.

The ratio of the time of the ascent and descent of the wing becomes much greater when the bird moves against the wind, suppose about forty-eight feet per second, or in rapid flight; and the velocity of the descent of the wings, and quantity of action expended, will augment in proportion. The great quantity of action expended in flight tends to confirm the views of Borelli respecting the vast power with which the pectoral muscles of birds are endowed. In small birds the oscillations are performed with such great rapidity, that they cannot be numbered by the eye; but in the finches and humming-birds, the oscillations of which produce a musical note, the pitch will enable us to determine with accuracy the number of oscillations in a given time. In large birds, the wings move through arcs of greater circles than in small ones, and the times of their periodic oscillations decrease in the same ratio, and may thus be more easily numbered: the areas of their wings, and the resistance which they encounter, bear some proportion to the greater weight of the body: but although theory ascribes to the wings a large number of oscillations, it by no means follows that they perform the exact number assigned at least for any lengthened period. On the contrary, we observe that many birds, such as the Woodpecker,* and most Insessores, give a few strokes of the wings by which the body acquires a projectile velocity sufficient to elevate it through a considerable space, and that when the impulse thus given is nearly expended, they repeat this action, and again suspend it. If they are moving horizontally, their progression is performed in a similar manner; the axis of the bird is inclined upwards at each impulse like a projectile, but the mean motion is horizontal. The curve described during each projection is a parabola. After a few strokes, during the ascent, the wings are folded until the bird has passed the vertex of the curve, and has descended to some distance on the opposite side, when they suddenly expand their wings again, and by a few strokes describe a new curve. In this mode of progression the velocity is very variable, being equal to that which a body would acquire by falling through one-fourth of the parameter of each point in the curve. Many large birds, such as the Rooks, Pigeons, &c. when descending from great heights expand their wings, and incline the axis of their bodies obliquely downwards, as in *fig.* 222.

Fig. 222.



In this case the air opposes sufficient resistance in a vertical direction upwards to keep in equilibrio the force of gravity acting upon the body vertically downwards, so that the motion of the bird becomes uniform, without requiring any movement of the wings.† Another mode of de-

where the formula gives 7.38, and observation from 2 to 3 flappings per second. It is worthy of remark, that by supposing V to be equal to the cube root, instead of the square root of $\frac{p+p^2}{p-q}\cdot\frac{2Wg}{\pi KA}$ the number of flappings in each of the last two cases by the formula, agrees very closely with the number determined by the mean of several observations.

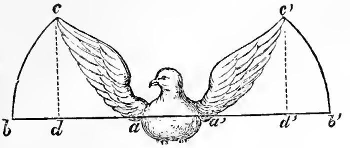
The quantity of force expended would be greater if the density of the air were less, but it would only increase in the ratio of 1.4 to 1 if the air were but half as dense. We may, therefore, conclude that the height to which a bird can raise itself is limited not so much by want of sufficient support in the resistance of the air as by the difficulty of respiring in too rare an atmosphere.

* The Rook appears to make from ten to fifteen, and the Pigeon from ten to twenty-three effective strokes of the wing in five seconds.

† The soft downy feathers which line the wings of the nocturnal rapacious birds, as the Owl, permit the wings to perform its evolutions during flight in search of their prey without noise. On the contrary, in the diurnal species of this order, which chase and capture their prey in open day, and where no secrecy would suffice, the feathers are strong, and their passage through the air is accompanied with a rushing noise.

scent is performed with greater celerity by elevating the wings at an angle of nearly 45° above the plane of the horizon, (as in *fig*.223,) by which

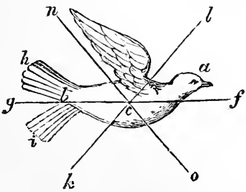
Fig. 223.



the resistance of the air, compared with the resistance to the wing when horizontal, is diminished in the ratio of radius to the cube of the sine of inclination, that is, as $a\ b$ to $d\ c^3$; consequently, a bird with its wings elevated at any angle to the horizontal plane will descend with greater velocity than when they are in the direction of $a\ b$. We most frequently observe that Pigeons elevate their wings in this manner until they arrive within a foot or two of the ground, when, to prevent the shock they would otherwise receive, owing to the velocity acquired during their descent, they suddenly turn their axis perpendicular, which had previously been parallel, to the direction of their motion, and by a few rapid strokes of the wing neutralize their momentum, and thus reach the ground with ease and safety. In order to produce lateral motion one wing oscillates more rapidly than the other, thereby causing the head to turn towards the side to which the latter wing is attached.

The tail of the bird performs the office of a rudder in steering its course; its plane being horizontal tends chiefly, as Borelli has demonstrated, to elevate and depress the head, rather than to turn the axis of the bird laterally. Let us, for instance, suppose that a bird, flying in the direction of its axis $g\ f$, (*fig.* 224) elevates

Fig. 224.



its tail into the position $b\ h$ parallel to $o\ n$, the resistance of the air will depress b towards k, and causing the bird to rotate on its centre of gravity c will elevate the head from a towards l; on the other hand, if the tail be depressed into the position $b\ i$, parallel to $l\ k$, by the resistance of the air, the point b will be raised towards n, and the head depressed towards o, consequently the direction of the bird in its mesial plane is regulated by the tail.* In the Grallatores the tail is short and its surface very small, and the function of a rudder is transferred to the legs, which are projected backwards in flight, to counterbalance the depressing weight of their long extended neck and head This fact was noticed by Aristotle.† The Swallows, which are almost always upon the wing, economise their muscular action by giving a few strokes with their wings, and by keeping them expanded, scud through the air with great velocity in chace of their prey; this interval of comparative repose must be of great service to them during their annual migrations across the sea to other countries. The velocity of some birds is very great. The Eider-duck is said to fly 90 miles in an hour, the Hawk 150. The great Albatross wafts itself across the Pacific Ocean apparently with untiring energy, owing to the vast muscular power with which it is endowed.

Flight of fish and other animals.—Besides insects and birds, there are some other animals capable of sustaining themselves during a short period in the air by means of membranous expansions or enlarged pectoral fins. The *Dactilopterus* and *Exocætus*, or flying fish, are enabled to raise themselves above the surface of the water by the action of their enormous pectoral fins; but Mr. Bennett, who appears to have particularly observed their motions, states that he has never seen these fishes sustain themselves for a longer period than thirty seconds, nor ever witnessed any vibration in their pectoral fins. Captain Basil Hall estimates their longest flight at about two hundred yards, and they have been sometimes known to rise above the surface of the water as high as twenty feet. The projectile force with which they emerge from the water determines their elevation, and the expanded pectoral fins merely sustain them for a brief interval.

The *Draco Volans* (*fig.* 225) is provided with a broad disc on each side, extending from the fore to the hinder extremities. It is covered by the skin, supported by the first six false ribs, and directed horizontally. This membranous disc expands and closes like a fan, and is elevated and depressed like the wings of birds to break their fall in descending from trees, but notwithstanding the extent and mobility of their wings, they are said to be incapable of raising themselves in the air, since their arms are detached, and neither enter into the composition of the wings, nor assist in their elevation or depression.

The area of the wings of the Draco volans (*fig.* 225)‡ estimated from the mesial section of the body is nearly 5·052 square inches. Another Draco volans which is preserved in spirits

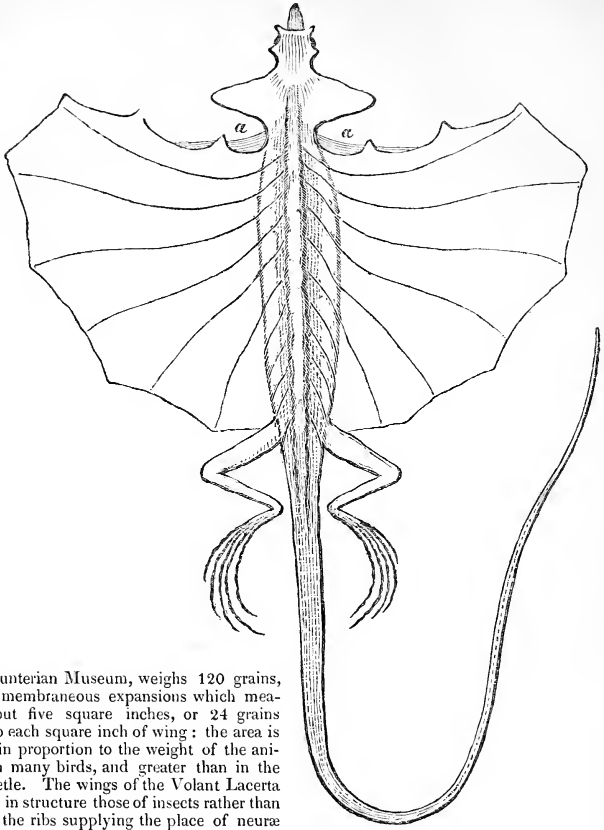
‡ In consequence of the specimen in the collection of Professor Grant, from which the annexed outline was made, being dry, its weight in the living state could not be ascertained.

Fig. 225.



in the Hunterian Museum, weighs 120 grains, and has membraneous expansions which measure about five square inches, or 24 grains weight to each square inch of wing: the area is as great in proportion to the weight of the animal as in many birds, and greater than in the Stag Beetle. The wings of the Volant Lacerta resemble in structure those of insects rather than of birds, the ribs supplying the place of neuræ in the former, and of the osseous framework of the anterior extremity in the latter. They have sufficient membraneous expansion for flight, provided the muscles which move them were so applied, and had sufficient force to elevate and depress them with the necessary velocity.

The Galeopithecus, or flying Cat, and the Pteromys, or flying Phalanger, are also furnished with lateral membranes extending from the atlantal to the sacral extremities, to both of which they are attached, but they are incapable of raising the animal in the air, and rather perform the office of parachutes than of true organs of progression.

The fossil remains of the Pterodactylus show that it was organized for flight; the phalanges of the ulnar finger being greatly elongated, apparently for supporting a membrane extending along the whole ulnar aspect of the arm and side of the body to the leg; a mechanism which enabled these animals to move through the air like birds. The four other fingers are free to answer the purpose of prehension, and are terminated by curved hooks like the thumb of the Bat.

The *Cheiroptera* are endowed with extensive powers of flight. The figure of the Bat presents an outline closely resembling that of birds, and calculated to offer the least resistance in the direction of their motion during flight. Their anterior extremities are constructed like wings, and their whole organization is adapted for aerial progression. The weight of the body compared to the area of their expanded wings is very small, and hence they have the power of raising and supporting themselves in the air. The osseous system is dense, but light, the sternum carinated, the scapulæ and clavicles fitted to support the wings, and to furnish a large surface for the attachment of the muscles which move them. The fore-arm, consisting almost solely of the radius, does not possess the power of pronation and supination, which would tend to lessen the resistance of the air to the wing in flight; the hand rotates on the radius by abduction and adduction, as in birds, so that, when folded, the little finger lies along the outside of the radius: the fingers, which are of great length, contribute to the expansion of the wing in flight; the thumb, which is not enclosed by the interdigital membrane, terminates by a strong hook for prehension, and for suspending the animal when in repose. The wing, taking its commencement from the neck, extends to the arm, feet, and tail. The interfemoral membrane, when developed, has its margin supported by an osseous extension from the calcanium; this membrane serves to elevate and depress the axis of the animal, its functions in this respect being analogous to that of the tail of birds. The elastic though delicate membrane of which the wings are composed, gives its stroke upon the air a great mechanical effect.

The proportion of the area of the wings to the weight of the body is greater in Bats than in many species of birds, and nearly approaches that in the Lepidopterous Insects, consequently their power of flight is very considerable.

Bats are capable of increasing the area of their wings during their descent, and of contracting them during their ascent by the alternate flexion, extension, abduction, and adduction of their elbows, fingers, and hands; and they can also vary their velocity, and consequently the resistance of the air during the elevation and depression of their wings in the same manner as birds. The ratios of the times and of the resistances during these movements of the wings, as likewise the number of their oscillations in a given time, may be computed very nearly by the formula applicable to the flight of birds, but owing to the extensive area of their wings compared with their weight, their oscillatory movements are comparatively slow. Their power of flight preponderates greatly over the force of gravity and the mass of their bodies, so that they are capable of flying with great ease, even when laden with one or two young ones. Their centres of gravity and magnitude lie beneath the axes of the articulation of the wings with the trunk, an arrangement which keeps them steady during flight. In repose they suspend themselves by their hind feet to some elevated object, from which on being alarmed they can fly off instantly. Their inferior extremities possess neither the length necessary to raise the body sufficiently to expand their wings, nor the power to project it vertically, like birds on taking flight; but by dropping suddenly from the point of suspension, they are enabled to expand their wings instantaneously and without obstruction in the air. Their velocity is so great that they can overtake and capture their insect food on the wing.

The amount of force requisite for aerial progression is so enormous, owing to the rarity of the atmosphere, that it would be impossible for a man to sustain himself in the air by means of his muscular strength alone, in any manner he is capable of applying it. It is calculated that a man can raise 13.25 lbs. avoird. to a height of 3.25 feet per second, and can continue this exertion for eight hours in the day, he will therefore exert a force capable of raising 381600 lbs. in the day to a height of 3.25 feet, or 47700 lbs. to a height of 26 feet, which, according to Chabrier, is the height to which a bird would raise itself in one second by the force it is obliged to exert in order to sustain itself in the air. Now, if we suppose the conditions necessary for flight in man to be the same as for birds, and that a man whose weight is 150 lbs. could concentrate the muscular power of a day's labour into as short a period as the accomplishment of this object required, we might find the time t, during which he could support himself in the air, from the following equation :—

$$150\, t = 47700,$$

hence $t = 318''$, or about five minutes.

It is, however, impossible that a man could concentrate the force of eight hours' labour into the short interval in which he would have to expend it when supporting himself in the air. The opinions of Borrelli and Chabrier agree with these views, and we are not so sanguine as to suppose with Bishop Wilkins, Sir G. Cayley, and others, that with the assistance of some mechanical contrivance men will some day be enabled to fly by the force of their muscular system. Such hypotheses, like the ancient stories of Dædalus and Icarus, &c. serve only to deceive the ignorant, amuse the credulous, and misdirect the human mind to attempt the accomplishment of impossible objects.

Sect. III. *Swimming.*—In swimming, as in flying, the fulcrum which affords the requisite resistance to the action of the locomotive organs of animals is the fluid medium in which they move, and as this medium yields to the force impressed on it by the organs, it is evident that these modes of locomotion are regulated by different principles from those applicable to animals whose progression is performed upon solids.

The reaction of the water in swimming is equal to the action impressed on it by the impulse of the locomotive organs; and if motion ensues, it results from a surplus force in the body in motion, equal to the difference between the force of the locomotive organs, and the resistance of the medium. The motion is accelerated as long as the force of the locomotive organs is greater than the resistance of the medium reacting against the surface of the animal. When the mean forces urging the animal forwards and the resisting force are in equilibrio, the motion becomes uniform. When these forces are at the maximum, the velocity is also at a maximum. If the weight of the animal be equal to that of the water it displaces, there will be no tendency to rise or sink, as the vertical force of the water upwards will be equal to the force of gravity upon the animal vertically downwards, and forces need only be employed to urge the centre of gravity forwards, backwards, or obliquely. The case is different with animals moving upon solids, where the weight of the body has to be supported as well as urged forwards by the instruments of progression. When the weight of the water displaced is greater than that of the animal, the body floats upon the surface, as in the Palmipedes; if, on the contrary, the weight of the animal be greater than that of the water displaced by its bulk, a vertical as well as a horizontal force is requisite, equal to the difference of the specific gravities of the animal and the water, to prevent its sinking during progression.*

The animal kingdom includes a vast number of species which are aquatic and constantly reside in ponds, lakes, rivers, and seas, having their general structures organized for inhabiting in these dense and resisting media, and their locomotive organs adapted for swimming. The number of these is far beyond the reach of calculation. Many of the larvæ of insects and the tadpoles of Amphibia, which in their adult state are either entirely or partially terrestrial, commence their career in water; in these not only the locomotive organs, but their respiratory systems undergo metamorphosis.

Ciliograde animals.—Under this denomination are comprehended the polygastric and rotatory animalcules, and many genera of the orders, such as the Porifera, Polypifera, and Acalephæ, whose locomotive organs are those minute, transparent, elastic, and very flexible conical filaments well known by the name of *Cilia.* The nature and structure of these organs have been fully detailed in the article Cilia, so as to render any further description here superfluous. The cilia act as levers, to which the water is the fulcrum.

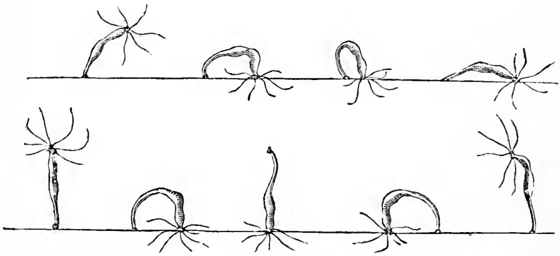
We may here refer to the Volvox, as affording a familiar example of ciliary locomotion. The figure of this animalcule being spherical, the cilia placed on its surface are all equidistant from its centre, but those possess the greatest mechanical power which are placed at equal distances from either pole of the animal's axis of rotation. The volvox is capable of changing its axis of revolution, or varying its direction, and appears to revolve across the field of the microscope like a planet over that of the telescope. In the Rotifera, or wheel-animalcules, the cilia are arranged in rows, around the margin of one or more circular discs, capable of being extended and retracted from the body.* When the tail of the animal is free, it moves by its cilia, pursues, and darts upon its prey in every direction. The Rotifera are also capable of crawling upon solids, by the extension and retraction of the body, the head and tail being alternately fixed points: they are also capable of revolving with great velocity on fixing themselves by the two posterior exsertile bulbs.

Porifera and Polypifera.—The Gorgona and Flustra are for a brief period capable of a ciliograde mode of progression. In the gemmules of sponges the cilia are spread over about two-thirds of the body. According to Grant, these zoophytes swim in a zigzag course, with the bulbous extremities directed forwards; their figure is pyriform; their migrations are of very brief duration, for after the lapse of a few days only, which are spent in seeking for some suitable locality, they fix themselves during the remainder of their lives.

The Actiniæ are capable of gliding upon the discs which form their bases of support. Reaumur asserts that they sometimes invert their position, and employ their tentacles as feet; they also diminish their specific gravity by augmenting their dimensions through the absorption of water; when detaching themselves at the base, they suffer the current of the sea to drift them from place to place.

Unlike most of the Polypes which are fixed, the Hydra viridis is capable of moving in the liquid medium which it inhabits (*fig.* 226). It

Fig. 226.



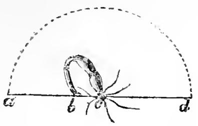
The Hydra viridis represented in its different stages of terrestrial locomotion, as figured by Trembley.

has three modes of progression; the first is accomplished by alternate flexions and extensions of the body; thus the head being fixed by the oral tentacles at *c* (*fig.* 227), the little disc terminating the anal extremity is drawn forwards from *a*, and fixed at *b*; the head is then raised and carried forwards, by the exension of the body, towards *d*; these two actions of flexion and extension complete a step, whose length is $= ac - bc$. The second mode of progression is performed

* See theory of Specific Gravities.

* See Ehrenberg's Infus. Berlin, 1830.

Fig. 227.



by a series of somersets, the tail being thrown over the head; if the head is first made the fixed point at *c*, as before, the tail will then describe the semicircle *a d*, which is twice the length of a step, or *ad* — *cd*, in the second movement; the tail being fixed at *d*, the head turns upon it as the centre of a new circle, and takes a position in advance of *d*, at a distance equal to *c d;* in these two actions the animal travels over a space equal to *a b*. In this manner the head and tail are advanced alternately. The third mode of progression is by far the most speedy. The Hydra having crawled to the surface of the water, lifts its tail above it to dry in the air, whereby it exerts a repulsive action on the water; this hydrostatic apparatus, acting as a float, is capable of suspending the body at the surface of the water in an inverted position; in this posture it rows itself along, or is drifted by the winds from point to point without effort.

In the Beroë Pileus, the motions are partly by cilia attached to rectangular laminæ, which are arranged in rows along the eight costæ (*h h*, *fig.* 32, vol. i.) of the elliptically-formed body. According to Dr. Grant, each row contains about forty laminæ, whose transverse section presents literally the appearance of the floats upon the paddle-wheel of a steam-boat: when the whole of these laminæ strike the water simultaneously, the resultant of their combined action is in the line of the projection of the axis of the animal, which is usually directed vertically. The direction, however, may be changed by the cilia acting partially, by which the inclination of the axis in the direction of the animal is determined.

The Physalus has the power of rendering itself either specifically lighter or heavier than water, by means of the inflation or contraction of its air-bladder; with the assistance of which the animal is enabled either to swim upon the surface, or sink, if alarmed, into the bosom of the ocean. The swimming-bladder of the Physalus is of considerable dimensions, and nearly of an elliptical figure, its longest axis being directed horizontally. The top of this bladder is furnished with a membranous lamina or crest, serving to increase the surface presented to the wind, before which it sails with considerable velocity. The Rhizophysa Melon, the Agalma Okenii, and the Diphyes Campanulifera, with most of the Acalephæ, having already been described and figured in the article Acalephæ, the reader is referred to them for further particulars, but it may be remarked that the progression of the Diphyes is performed upon the principle of the *Syringogrades*, merely by the reception and expulsion of water by their two truncated sections, which, taking place alternately, gives the animal a mean uniform motion of considerable velocity.*

Cirrigrade animals.—Unlike the entirely soft gelatinous forms which compose the Pulmograde and Ciliograde Acalephæ, the Cirrigrade group have an internal solid skeleton to support their soft and delicate exterior tissues. In the Porpita this skeleton is composed of a flat, circular, semicartilaginous plate, which lies horizontally on the surface of the water; to this plate are appended numerous cirrhi which perform the office of oars in rowing the animal on the surface of the sea: the Porpita is permeated with pores, which being filled with air render it of less density than the water upon which it floats. The Velella Limbosa has a thin perpendicular crest resting obliquely upon the horizontal plate, which being elevated above the water, and presenting a considerable surface to the wind, serves as a sail. In the Rataria cordata,† the crest is furnished with muscular fibres, by which the sail can be elevated or lowered at pleasure; but this does not take place without altering at the same time the centre of gravity; for the position of the body is nearly reversed when the crest is lowered, but it recovers itself on the crest being elevated.

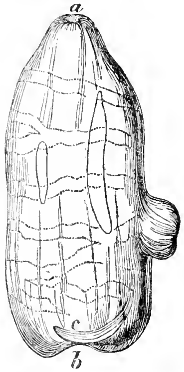
Pulmograde animals.—The umbelliform or mushroom-shaped disc of the Rhizostoma being capable of expansion and contraction at the will of the animal, is employed not only to keep the body (which is specifically heavier than water) at its surface, but also to propel it along. When the plane of the disc lies horizontally, and its whole margin contracts simultaneously, the percussion given to the water is perpendicular to the plane, or in a vertical direction, and the animal receives an ascending impulse equal to the force of the reaction caused by the displacement of the water. In moving horizontally, the centre of the disc is turned in that direction, and the animal can also accelerate its descent by the assistance of the disc. The contractions of the disc are isochronous, and repeated about fifteen times in a minute,‡ or $15 \times 60 = 900$ times in an hour. The convex surface of the Aurelia aurita is directed forwards in progression; in this position the whole margin of the disc is called into action, by which the locomotive force is increased, and owing to the figure of the disc the resistance of the water is diminished, and the speed is consequently accelerated.

Syringograde animals.— Under this denomination we shall include the Holothuria, the Salpæ, and the larvæ of those insects whose progression is effected by the alternate reception and expulsion of water to and from their respiratory organs by an action similar to that of the syringe. Independently of moving upon solids by means of its tubular feet, the Holothuria, according to Muller, is capable of drawing water into its cloacal aperture, and by means of its muscular system, of expelling it from its respiratory

* See vol. i. p. 35 *et seq.*
† Vide Art. Acalephæ, vol. i. p. 40, fig. 12.
‡ See Grant's Lectures, Lancet, 1833.

organs with sufficient force to propel itself through the surrounding medium. The progression of the Salpa cristata is effected by drawing water into its body, at an opening situated in the posterior segment of the mantle, where a valve (*fig.* 228 *c*) is placed to pre-

Fig. 228.



Salpa cristata.

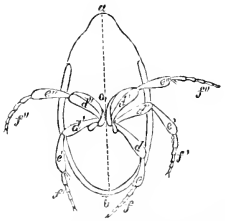
vent its returning by the same aperture; the mantle having been distended by the water, contracts upon it, by which action it is expelled at an opening situated at the side of the mouth (*a*); its progression is retrograde, or in the direction of *a b*, opposite to that of the fluid in *b a*.

The larvæ of some Dragon Flies, such as the Ashna and Libellula, draw in and expel the water alternately at the anus, which they occasionally lift out of the water, and project a small stream at a distance above the level of its surface: the hydrodynamic effect of these actions is to give a locomotive impulse to the centre of gravity in a direction opposite to that of the ejected fluid. The reaction of the water, which is equal to the action of the ejected stream, is not only sufficient to overcome the resistance of the surrounding medium and the inertia of the body of the animal, but also to drive it along. The velocity of the Syringogrades is accelerated during the expulsion of the water, and retarded during its reception; consequently the motion is never uniform.

The *Vermiform* animals are for the most part destitute of distinct locomotive organs, yet, owing to the flexibility of their lengthened and usually cylindrical bodies, they swim with great facility. They glide by a series of lateral undulatory movements of the body, with which they strike the water obliquely backwards, and with equal force on each side of the axis of motion, so that the force impressed on the water is translated to the centre of gravity of the animal in an opposite direction forwards; the composition of all the forces giving a resultant the direction of which coincides with the axis of motion. Many serpents whose habits are chiefly terrestrial, swim with the head elevated above the surface of the water; others glide entirely beneath it. Some of the Entozoa, as the *Tæniæ*, and, among the Annelides, the Planariæ, when immersed in warm water, swim by similar undulations of the body; the latter, however, with the ventral aspect upwards. In the Ophidian Hydrophyli, or water-snakes, the tail is flattened; and its planes being directed vertically, give it the properties of a powerful oar, in striking the water by lateral oscillations. In many chetopod Annelides, the setæ and cirrhi form numerous and complex external organs of progression. The *Terebella* has four rows of setæ in tufts; the dorsal row projecting in the horizontal, the ventral in the vertical plane. They extend along the whole of the elongated subquadrangular-shaped body. In the Eunice Gigantea, which grows to the length of more than ten feet, each ring is furnished with two lateral packets of bristles, and two cirrhi. In the Nereis nuntia the locomotive organs are complex and greatly multiplied. The cirrhi and setæ may propel the body forwards, independently of those undulatory movements which are indispensable for the progression of the apodous Annelides.

Aquatic insects.—The perfect insects swim like quadrupeds and birds, by the alternate flexion and extension of their legs. Amongst the aquatic insects the Dytiscus is one of the best organized for swimming; its figure resembling that of a boat, being calculated to glide through the water with little resistance. The posterior legs are greatly developed, and they are moved by powerful muscles performing the office of oars, and are the principal instruments used in swimming. Their movements forwards are made in a plane nearly horizontal. The haunches being fixed to the thorax, give firmness and precision to these legs, which do not differ materially from those of other Coleoptera, with the exception of the tarsi, which are much flattened, and present their broad surfaces to the water. They are furnished with rows of stiff hairs, which bend when the leg is carried forwards, and become straight when its movement is vigorously reversed, thus increasing the

Fig. 229.

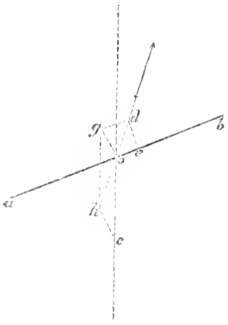


The Dytiscus, from Straus-Durckheim, showing the various positions which the posterior legs take in swimming.

effect of the stroke. In the back stroke, the thigh (*d*, *fig.* 229) moves first, describing an arc of a circle about their iliac extremity, from *d* to *d′* and *d″* successively. During this movement the legs *e* and tarsi *f* are flexed passively, and carried forwards to *c′*, *f′*, so as to act with little effect on the water. The two thighs *d″ d″* begin to approach their greatest flexion forwards, the legs *c′ c′* and the phalanges *f″ f″* extend in succession, so that the water opposes resistance to only one of them at a time. The tarsi (*f″*) having been completely extended outwards, the two legs are suddenly carried backwards, pressing on the water, with the entire plane of the tarsi, and as the silky fringes which cover the phalanges are extended at the same instant, their surface is considerably augmented. The other parts of the two legs pressing upon the tarsi, as in the walk or the leap, projects the body forward in the direction of its axis. In walking, the two members of the same pair act alternately, in order to serve, each in its turn, as a support to the centre of gravity. In swimming, on the contrary, the body being supported by the water, the two members move simultaneously, in order to give the greater impulse, and it is in this respect that swimming differs essentially from walking, and more nearly approaches leaping. The middle legs of the Dytiscus act in a manner similar to the posterior, but being shorter and weaker, contribute little towards accelerating the movements of the animal; the anterior pair appear to be used chiefly for the purpose of altering the direction of its motion.

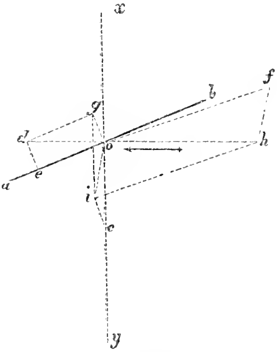
The motions of insects in the water may be thus explained: let *a b* (*fig.* 230,) be the axis of the body passing through the centre of gravity *o*; and let *c o* be the excess of the specific gravity of the water over that of the insect, acting in a vertical direction upwards; and *d o* the resistance of the water to the insect moving in a direction oblique to the axis of the body; this

Fig. 230.



latter force is decomposed into two forces, one in *d g* parallel, and the other in *d e* or *g o* perpendicular to the body, the former of which is lost, and the latter forces it obliquely downwards and backwards; this force being combined with the force of the water *c o* produces a resultant in *h o*, opposite to *d o*, which is the force by which the insect ascends passively. On the other hand, when the insect moves horizontally with its axis inclined in *a b*, and its centre of gravity in *o*, (*fig.* 231,) let its

Fig. 231.



A figure from Straus-Dürckheim, to illustrate the movements of insects swimming horizontally.

velocity be represented by *h o*, so that the force in this direction may be the resultant of the forces of the locomotive organs, of the water *c o*, and of the resistance which it opposes to the motion of the body in the direction of *d o*, opposite to *h o*. The resistance of the liquid in *d o*, acting obliquely upon the plane of the body, *a b*, (which is known from the velocity of the body and the inclination of its axis to the horizontal plane,) may be decomposed into two forces, one in *d g* or *e o* parallel, and the other in *d e* or *g o* perpendicular to the body; the former is ineffective, and the latter tends to force the body backwards and downwards. The force *g o*, being combined with that of the water *c o*, produces the resultant *i o*, which, with the force of the oars, must give the two components of *h o*. Completing the parallelogram of forces, of which *h o* is the diagonal, we find that the legs must generate a force represented in magnitude and direction by *f o*, and it is in the direction of this component, or, more correctly, in a line parallel to it, that the centre of force of the feet ought to act, which is in fact the case.

The *Hydrophilus* has nearly the same form as the Dytiscus, but is not quite so well organized for swimming. The *Gyrinus* also, as well as the Hydrophilus, swims in conformity with the same principles as the Dytiscus. The *Nepa*, being ill organized for swimming, usually walks in the water. The *Hydrometra* being so light, and having a little globule of air attached to its feet, has the power of swimming on the water without sinking. The *Notonecta*, in which the centre of gravity lies above the centre of magnitude, swims in an inverted position; it is propelled exclusively by its posterior legs, which are lengthened, and move in a plane parallel to the axis of the body. The thighs, legs, and tarsi are nearly of equal length; the two phalanges, which are slightly flattened, are furnished with hairs to strike the water with greater force, and to vary the surface presented in the effective back strokes. When the insect is poised freely in the water, its centre of gravity lies in the vertical line, passing downwards from the centre of the figure. From the singular circumstance of its swimming on its back, it has derived the appellation of Notonecta.

Decapods.—In the Crustaceous Macrourous Decapods, such as the Lobster, Prawn, and Shrimp, the tail is prolonged, and equals the length of the body. It is the principal organ of locomotion, and the seven segments which compose it are nearly of a semi-elliptical form, the terminal being furnished on each side with laminæ, which the animal spreads out transversely like a fan, in order to produce a greater surface in striking the water. At the dorsal aspect, the segments of the tail are locked before its extension is completed, but on the abdominal aspect there is greater freedom of motion. The segments of the tail are articulated with each other on both sides by ginglymoid joints, of which the axes of rotation are directed perpendicularly to the plane of the mesial section, consequently their motions are restricted to one plane. A slight eccentricity, however, in the direction of the articulating axes of the joints permits a limited obliquity of motion in the tail, but at the expense of muscular power. In swimming, the convex surface of the tail is presented to the water during the back stroke, and the concave ventral surface in the effective stroke, by which the force translated to the centre of gravity in flexion is to that of extension nearly as two to one.* During each flexion of the tail the animal is propelled backwards, and its velocity is accelerated, but during each extension it is retarded, so that its movement is retrograde and accomplished by a succession of impulses. In the swimming Decapods, the thoracic stemmata are laminated to assist in progression.

The Cephalopods.—The Cephalopods swim according to the same principles as the Holothuria, by admitting water into the interior of the body and jetting it through the funnel with sufficient velocity to communicate a locomotive retrograde impulse to the animal, which enables it to traverse the sea with considerable speed. From the time of Aristotle to that of Cuvier, the Argonaut, or Paper-Nautilus, has been supposed to have its slight and delicate monothalamus shell designed for a boat, and the broad expanded membranes terminating the two dorsal feet organized for sails; but, whatever poetry may have been associated with this view, must be abandoned by the Zoologist for the more modern and more physiological conclusions to be deduced from the researches of M. Sander Rang* and Madame Power, who have discovered and assigned the true function of these expansions, the fabrication of the shell.

Pteropoda.—Amongst Pteropods, the Clio Borealis presents a conical shaped body about an inch long; its locomotive organs consist of two uniform expansions attached on each side of the neck, the planes of which lie parallel to the axis of the body. According to Eschricht, the fins are composed of one muscular fasciculus, which passes through the neck, and this muscle acts in a manner resembling the principle of the double-paddled oar with which the Greenlander steers his course on the surface of the same seas wherein the Clio is found. The inclination of the planes of the fins to that of the axis of the body determines the direction of the animal. The Clio, however, is destitute of organs of prehension, and consequently incapable of fixing itself to solids; it must therefore either remain at the bottom of the sea or paddle its course upon the dense medium which it inhabits.

Pisces.—Amongst the great multitude of animals moving in seas, rivers, and lakes, Fishes next claim our attention. The medium in which fishes move being nearly of the same specific gravity as themselves, they are sustained by such an amount of hydrostatic pressure as almost to neutralize the force of gravity upon their mass, so that organs of progression, calculated to support nearly their whole weight, such as occur in terrestrial animals moving on solids and in a rarer medium, are unnecessary. We observe also that as they are sustained on all sides by great hydrostatic pressure, they do not require their organs of support to be of that magnitude and density which are requisite to terrestrial Mammalia for resisting the shocks of external forces. In the osseous fishes the bones are, therefore, light and elastic, and in the cartilaginous fishes the organs of support are still more light and flexible. The specific gravity of fishes, although small, is greater than unity, consequently we know, by hydrostatic principles, that without continued muscular effort, or some provision for rendering themselves of equal or less specific gravity than the water, they must sink to the bottom and remain there;† but the economy of a great number of fishes requires that they should sustain themselves permanently far above the solids forming the beds of rivers, lakes, and seas, and that they should be enabled to rise to the surface, or sink into the depths of the ocean in pursuit of their prey. As this, however, would otherwise require a vast and never-ceasing play of muscular action during life, Nature has provided them with an apparatus which prevents this waste of muscular energy by the introduction into their system of the *air-bladder*. This hydrostatic apparatus is of various shapes, but always of sufficient dimensions to contain, when it is distended, as many cubic inches of air as will render the fish specifically

* See Principles of Resistance of Curved Surfaces moving in Fluids.

* Vide Guerin's Magazin de Zoologie.

† See Theory of Specific Gravities, sect. 1, p. 412.

lighter than water, and as the specific gravities of air and water are to each other nearly as 1 to 815, a small bulk is sufficient to render the lesser fishes lighter than the medium they inhabit. The position of the air-bladder being immediately under the spine and above the centre of gravity causes the fish to rise without the danger of turning over on its back. Those fishes which are furnished with an air-bladder are capable of either renewing, expelling, compressing, or dilating its aerial contents, and of varying its area so as to rise, sink, or remain in equilibrio. The air-bladder becomes by this means an important auxiliary organ of locomotion, and affords an illustration of one of the many evidences of design in the primary formation of aquatic animals.

The *Diodons* and *Tetrodons* render themselves buoyant by swallowing air, which filling the first stomach becomes inflated like a balloon; but as the gastric reservoir lies below the centre of gravity, the bodies roll over in an inverted position, and are driven in the direction of the winds and tides without the power of directing their course.* The forms of fishes are considerably diversified, being spherical in the globe *tetrodon;* an elongated cylinder in the Eel; compressed in the Dory and Spah; flattened into planes parallel to the mesial section in the Pleuronectidæ; elliptical in the Salmonidæ, Scomberidæ, and Mugilidæ. In nearly all the orders of fishes the surface presented to the water by the head and shoulders inclines more or less to the vertebral axis of the fish, which coincides with the axis of motion, and therefore is adapted to offer resistance, which varies with the angle of inclination.

In the Salmon, Cod, and Mackerel the form of the body approximates to that which is considered by mathematicians to offer the least resistance to the surrounding medium. The organs of support are developed principally in the plane of the mesial section, and consist of superior and inferior spinous, interspinous, dorsal, and ventral fin elements, the projections of which prevent motion of the vertebral axis in the plane of the mesial section. The vertebræ are short, numerous, and, towards the caudal extremity, destitute of transverse processes, an arrangement which gives the tail a considerable degree of lateral motion; owing to which it becomes the most essential organ of locomotion. The locomotive organs of fishes are the fins and tail; the pectoral fins represent the anterior, and the ventral the posterior extremities of the higher orders of Mammalia. In the Cod, the legs are absolutely in front of the arms, being suspended under the throat. The Percidæ, which are provided with two dorsal, two pectoral, and two ventral, as well as anal and caudal fins, have the greatest number of locomotive organs. The planes of the dorsal and anal fins are in the mesial section of the fish, and being restricted in that plane by a kind of ginglymoid joint, are capable only of elevation and depression. In the Cod, Halibut, and Gurnard, the action of these fins serves merely to increase or diminish the lateral surfaces of the fish, so as to prevent any tendency in the animal either to oscillate laterally, or turn upon its vertebral axis into an inverted position, which it would be inclined to do without some muscular effort, since in the erect posture the centre of gravity lies above the centre of figure.* The plane of each ventral fin is in general nearly horizontal, and perpendicular to that of the caudal; their action serves to balance the body, to incline it on either side, when one fin only acts, and to elevate and depress the fish by their joint effort.† In many fishes the pectoral fins being at right angles to the tail and vertical, act horizontally, and communicate either a progressive or a retrograde impulse to the body, thus assisting the action of the tail; if they are both retained in an extended position, they will retard the velocity of the fish; if one pectoral fin only is extended, it will turn the fish in a curve towards that side; if the other only, it will turn it on the opposite side: they thus perform the office of a rudder. When the planes of the pectoral fins are directed obliquely forwards and upwards, they communicate an ascending and a retarding impulse to the fish, but the amount of retardation is compensated by the power which the fish acquires of ascending. When the caudal, ventral, and oblique pectoral fins move simultaneously, there result three forces acting in different planes, whose intensities, estimated in directions perpendicular to those planes, are severally proportional to the products of their areas multiplied into the squares of their velocities;‡ the resultant of these forces may be obtained by the law of the parallelogram of forces.§

In the Rays, the pectoral fins are developed to an enormous extent, and being directed horizontally, their action is vertical, like the wings of a bird. They are furnished with a great number of joints, which endow them with considerable mobility; they have the power to increase the surface of the fin during depression, and to diminish it during elevation. The disc of the ventral fins lies in the same plane as the pectoral, and acts in a similar manner, but the plane of the caudal fin is at right angles to them. The depression of the pectoral and ventral fins elevates the fish, whilst the lateral motions of the tail propel it forwards. The area of the pectoral fins in the Rays is very great compared with that of the caudal; and

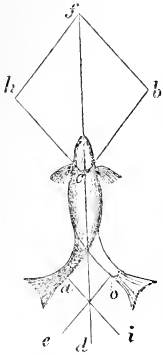
the intensity of their action (all other things remaining the same) must be proportional to their areas respectively. Sometimes the Rays glide sideways, in which motion the pectoral and caudal fins exchange their office, the former striking horizontally, and the latter vertically, the result of which may be obtained by the composition of forces, when their directions and intensities are given. The Rays, being destitute of an air-bladder, require a much greater force in the vertical direction upwards to sustain themselves in swimming; hence the necessity for the power and mobility of the pectoral fins which we find conferred on them. The great lateral development of the surface of the Rays compared with their depth, and the great depth of the Pleuronectides compared with their breadth, entitle the former, rather than the latter, as Mr. Yarrell justly observes, to the appellation of *flat fish*.

The first movement of a fish from a state of rest is usually produced by the flexion of its tail, as to *a*, *fig*. 232; during this action the centre of gravity (*c*) recedes slightly from its previous position; the tail being flexed into the position *a*, is forcibly extended by the muscles on the opposite side, in the direction of the line *a i*, perpendicular to its plane. The force of its action upon the water in *a i* is translated to the body of the fish in *i a*, causing the centre of gravity *c* to move obliquely forwards in the direction of *c h*, parallel to *i a*. The tail having reached the mesial line *c d*, its power of urging the centre of gravity forwards not only ceases, but during its flexion in *e o*, it acts backwards in the direction of *o e*; having reached the point *o*, it is again forcibly extended in the line *o e*, causing an impulse on the centre of gravity in *c b*, parallel to *o e*; if the two forces *c h* and *c b* acted simultaneously, we should obtain the resultant *c f*, but as they do not, the point *c* will not move exactly in the right line *c f*, but in a curved line, which lies evenly between *d c f* and a line drawn parallel to it through *h*. The fish being in motion, the tail describes the arc of an ellipse,* whereas if it were stationary, it would describe the arc of a circle. If we suppose the force resulting from the flexion of the tail to be so great as to neutralise the velocity which the centre of gravity had acquired during its extension, the result would be a state of rest whenever the tail reached the points *a* and *o*, and a greater force than this would

Fig. 232.



* Borelli, loco cit. prop. 24, p. 259.

cause it to recede; which, according to Sir John Lubbock,* is the case, although it has never yet been detected in the movements of the living animal. The minute investigation of this subject, however, embraces a very complex analysis.† There are several circumstances which militate against the hypothesis of Sir John Lubbock; first, the muscles which move the tail are capable of varying its surface during flexion and extension, and of contracting it during the former and expanding it during the latter action, by which the resistance is proportionably varied. Secondly, the muscles of the tail incline its plane to the direction of its motion during flexion, and present its plane perpendicularly to that direction during extension, which causes the effective resistances in the two strokes to be to each other as $1 : s^3$, where s is the sine of the inclination of the tail to the horizon. Thirdly, according to Dr. Roget, the water having been set in motion during the extension of the tail, in the same direction, offers comparatively but little resistance in flexion; on the contrary, when the motion of the tail is reversed, the water meeting it in an opposite direction produces a resistance proportional to the sum of the squares of the two velocities. These are so many causes which contribute to diminish the force of the tail during its flexion, without producing a retrograde motion in the fish. The same demonstration serves when the plane of the tail is directed horizontally, as in the Cetacea and Flat Fishes, but the impulse given must be estimated in a vertical instead of a horizontal plane. The velocity of some fishes is very considerable, and often maintained for lengthened periods. According to Lacepede, that of the Salmon is eight metres, or 26·24 feet in a second; others are said also to travel upwards of sixteen miles in an hour; the Shark, for instance, will often accompany and gambol around a ship in full sail across the Atlantic. In those fishes which have the greatest velocity the tail is forked, the area is in the inverse ratio of the distance from the centre of gravity; in these the centre of force is one half the distance from the centre of motion. When the tail presents a triangular surface, of which the apex is the centre of motion, the centre of force is three-fourths the distance of its base from the axis of oscillation. With this form of tail the muscles act at a mechanical disadvantage, and consequently the animal moves very slowly.

If we consider the density of the medium in which these animals move, the resistance which it opposes to their bodies, and the long periods during which they will continue in progression, we may form some idea of the great energy with which their muscular system is endowed.

Aquatic Birds.—In the Aquatic Birds, the thorax and abdominal regions present a form

* See Dr. Roget's Bridgewater Treatise, vol. i. p. 369.

† See Chabrier, Mém. de l'Acad. des Sc. tom. xi. In this paper formulæ are given for finding the velocity of the centre of the tail and the quantity of action expended in swimming.

resembling the keel of a boat. The feathers are furnished with an oleaginous secretion, which prevents the water from penetrating to the skin; they also enlarge the bulk of the bird without very sensibly increasing its weight. In the Palmipedes, the osseous system, though more dense and less permeated with air than in birds destined for long and continued flight, is yet so light as to render their specific gravity considerably less than water, so that a large proportion of the body is sustained above its level by hydrostatic pressure alone. The interdigital membranes which give an expanded surface to the feet of these birds, acting at the end of the long lever, formed by the metatarsal bone, enable them to strike the water with considerable force.* In the effective stroke produced by the extension of the legs, the flat surface of the feet is presented to the water in the direction of motion, whilst in the back stroke they are drawn forwards very obliquely and with less force. In the former action, the centre of gravity is accelerated, but during the latter it is retarded, so that there results a succession of impulses and a variable motion. The Swan and other Palmipedes sometimes spread out their wings as a sail, upon which the wind acts with sufficient force to propel them along without the expenditure of any muscular power. The specific gravity of birds, being much less than unity, enables them to glide upon the surface of the water without any expenditure of muscular action in the vertical, consequently it is required only in the horizontal direction.

Quadrupeds.—Many quadrupeds have their feet palmated to afford a larger surface for striking the water in swimming. Many of the Saurian, Batrachian, and Chelonian tribes have their feet thus organized, though the Caymans are semipalmated. The lateral direction of the locomotive organs of the three former orders enables them to give an oblique stroke downwards and backwards, so as to communicate an ascending as well as a horizontal impulse to the centre of gravity, and thus to prevent their sinking whilst they are urged forwards. In the common Otter the feet are also palmated, a construction which enables them to move in the water with surprising agility, and with sufficient velocity to overtake and capture the fish on which they prey. In a similar manner the feet of the Newfoundland Dog are also furnished with interdigital membranes, but owing to the number of their respiratory movements in a minute they are incapable of remaining below the surface of the water for lengthened periods. The Ruminantia, Carnivora, and Pachydermata, being all of less specific gravity than water, can swim with facility, and their locomotive organs, acting as in terrestrial progression, render swimming a task of easy accomplishment. Quadrupeds swim by the alternate extension and flexion of their legs; the effective stroke is performed during extension, and the back stroke during flexion, presenting in the former a larger area to the water than in the latter. In consequence of the difference of their specific gravities, the Horse is capable of swimming even when loaded with the weight of a man, with a large proportion of its body above the surface of the water. The feet of the Solidunguli are well formed for striking the water, the flat portions of which are employed in the effective and the convex in the back stroke, so that the proportion of the resistance of the water in these two strokes, owing to the figure of the foot, are to each other nearly as two to one.*

Man.—The figure of the human body, the position of the respiratory apertures, the number of respiratory movements made in a a minute, the different plane in which the locomotive organs usually act in terrestrial progression, and the small surfaces which the hand and feet present to the water, contribute to render man the least adapted of almost all animals for swimming. The specific gravity varies in different individuals; it is rather greater than water when the chest is nearly exhausted, and less when well expanded with air; hence a man has always an hydrostatic apparatus which will keep him floating, if he has the knowledge of this fact and sufficient presence of mind to employ it. The density and temperature of water produce at the moment of immersion an involuntary expulsion of air from the chest, added to which the consequent alarm and misdirected struggles facilitate the fatal catastrophe of drowning. In swimming, the hands and feet are employed so as to present the least surface to the water in the back and the greatest in the effective stroke; in the former the hands are brought near the mesial plane, with the palmar surfaces parallel to each other; they are then thrust forward by the extension of the arm, with the points of the fingers in advance to cut the water with the least resistance; when the hands have nearly reached their greatest distance from the centre of gravity, they are rotated by pronation, so that the palms are directed at an oblique angle outwards and downwards; they are then forced backwards by the abduction of the whole arm through a large arc of a circle, having the shoulder-joint for its centre, and the length of the arm for its radius; the fore-arm is then flexed, and carried into its former position preparatory to making another stroke. During the extension of the arm, the feet are drawn towards the centre of gravity, with their convex surface directed obliquely backwards by the extension of the ankle and flexion of the hip and knee joints, and during the adduction of the arm the flat surfaces of the feet are driven forcibly backwards and downwards by the sudden extension of the leg. From the ratio of the areas of the hands and feet, and the ratio of the difference of their velocities in the two strokes, there results such a preponderance of the force in the vertical direction upwards and in the horizontal direction forwards as is sufficient to keep the respiratory openings above the surface of the

* See Principles of the Resistance of Fluids.

* See Resistance of Fluids.

water, and to overcome the resistance which the water opposes to the motion of the body, due to its figure and velocity. In resisting media, both the facility with which bodies immersed are supported, and the difficulty of moving through them, increase with the density of the medium: this arises from the increased resistance which the particles oppose to their displacement; hence, according to Borelli, fishes expend, in order to acquire a given velocity, nearly twice as much animal power as birds, but are supported in the fluid without any exertion, whereas birds, as we have seen, are obliged to use considerable force to sustain themselves in the air.*

Sect. IV. *Progression on solids.*—The progressive motions of animals on solids are accomplished with much less expenditure of muscular action than is employed by animals in swimming or flying. In the various movements of animals upon solids the reaction of the ground is always equal and opposite to the quantity of muscular action impressed on it.† The velocity being equal, muscular action increases as the resistance of the solids decreases; hence the augmentation of labour in walking on a loamy or soft soil, such as the sands on the sea-shore. If an animal were projected into space, and moving in an unresisting medium, no effort of its limbs would ever enable it to change either the velocity or direction of the motion of its centre of gravity. From these dynamic considerations we perceive the importance of a surrounding resisting medium to animal progression. We shall now trace the modes of terrestrial progression from the lower forms of the animal kingdom successively through the intermediate groups, to man.

Radiata.—In the general outline of the Echinodermata we observe great diversity in the structure of the organs of support and locomotion. The Crinoidea belong most generally to those forms of the Echinodermata which are permanently fixed. Amongst the Asterioidea, in the Comatula, the locomotive organs consist of long, complicated, flexible arms radiating from a common centre, and subdividing into numerous filaments covered with spines, which perform the office of so many legs, enabling the animal to drag itself along the bottom of the sea, or of so many tentacula to lay hold of surrounding solids or to seize their prey. In the Ophiura the rays are of considerable length, being composed of a great number of pieces curiously imbricated and connected together by ligaments; they are flexible and moveable in every direction, and act not only as legs for crawling on the ground but also as fins, which, by a kind of undulatory movement, enable the animal to swim during short intervals. In the Asterias the five rays diverge at nearly five equal angles from the axis of revolution. In the Sea-star each ray, according to Reaumur, is composed of seven hundred calcareous plates, of which there are about three thousand five hundred in the whole animal. The rays of the Asterias do not possess the flexibility of those of the Comatula or Gorgonia, and of themselves would be insufficient to propel the animal along. Nature has therefore substituted other organs of progression in tubular, retractile, fleshy suckers, protruded from oblique ambulacral perforations, by means of which the animal is dragged along the bottom of the sea or upon the vertical surfaces of submarine rocks. If an Asterias left to all appearance motionless and inanimate by the retiring waves, be picked up from the beach, and placed in a large glass jar filled with sea-water, an astonishing spectacle will be observed. "Slowly," says Professor Rymer Jones, "the rays expand to their full stretch; hundreds of feet protrude through the ambulacral apertures, and each apparently possessed of independent action, fixes itself to the sides of the vessel; as the animal begins its march, the numerous suckers are all soon employed in fixing and detaching themselves alternately, some remaining adherent, whilst others change their positions; and thus by an equable gliding motion the star-fish climbs the side of the glass." The progression of the Asterias is laboured and exceedingly slow, and ill adapted for traversing such surfaces as the rough shingles of the sea-shore.

Echinida.—The Echinus Esculentus is one of the most complicated and elaborately formed species of the whole Echinodermata; its figure is spherical: the five pairs of arched ambulacral, and five pairs of tubercular columns, are joined to each other by zigzag sutures. The numerous spines are connected to the tubercles by a ball and socket articulation. According to Dr. Grant, the skeleton is composed of more than ten thousand pieces, the spines acting as so many inflexible levers, and the numerous suckers protruding through the oblique ambulacral foramina, as so many feet, form a double set of organs for progression.*

In the Echinus, the spines being perpendicular to the shell, elevate its centre of gravity (which, on account of its globular figure, is in the centre of the shell) far above the plane of motion, protect the shell from internal injury, and increase the diameter of the whole sphere, with respect to that of the shell alone, by twice the mean length of the spines. From the nature of their articulations, the spines are capable of moving in every direction upon their tubercular attachments; but these alone would be insufficient to enable these animals to climb the sides of submarine rocks and vertical precipices in search of shell-fish on which they prey; but by the aid of their tubular feet, which they have the power of extending beyond the spines, we behold in the Echini the

* See Borelli, p. 260.

† Barthez, in opposition to Euler, Borelli, and others, denies that *reaction* is the cause of progressive motion on solids, but in the explanation which he gives of it it is difficult to understand his reasoning, without taking into account the *resistance* of the ground.

* Grant's Outlines of Com. Anat. p. 18.

curious spectacle of globular bodies moving in direct opposition to the force of gravity. The structure of this interesting animal in a mechanical point of view is worthy the profound attention of the mathematician, as well as of the anatomist and physiologist.

SECT. IV. *Annelida.*—The terrestrial Annelides, such as the Lumbrici or Earth-worms, have the body cylindrical, and divided into upwards of one hundred and twenty segments, which permit of extension and contraction, with the power also of curving the trunk vertically and horizontally, according to the play of the muscular system. The progression of the Lumbrici is aided by their retractile setæ, or conical spines, eight of which are attached to each ring, consequently there are as many or more than $8 \times 120 = 960$ of these setæ in a single worm, to assist its locomotion. As many of the Lumbrici attain the length of nearly twelve inches, there must be about twelve rings or segments in an inch of the body taken longitudinally; now each ring being articulated with great freedom of motion, and the integuments being soft, flexible, and elastic, the trunk possesses very great mobility.

The locomotion of the Lumbrici is simple, and performed in the following manner. When the animal is about to advance, the head is raised, and about fifteen or twenty of the anterior segments are extended and placed firmly upon the plane of position; the setæ and rings assist in fixing the segment in advance; this being effected, the next fifteen or twenty rings are drawn forwards, and the setæ are again fixed in a similar manner; subsequently a third and fourth series successively complete the progression of a step. The space taken at each advance depends on the energy and magnitude of the animal, and the nature of the surface on which the movements are performed. Some Lumbrici, about six inches in length, having been placed upon a smooth surface, performed a distance equal to their own length at six or seven complete steps, taking about one inch at each advance; this occupied nearly one minute of time, being a velocity of progression of about thirty feet per hour. The smoothness of the surface retarded the celerity of their movements in consequence of the setæ being incapable of fixing the segments against any points with sufficient power to enable them to draw the succeeding segments forward; under these circumstances the mouth was observed to be substituted, and to lay firm hold of the surface, whilst the anterior segments were drawn forwards. The Lumbrici are capable of ascending a plane inclined at an angle of 45° to the horizon, provided its surface presents sufficient irregularities for the application of the rings and setæ. The centre of gravity of the Lumbrici is very near the middle of their length. The cylindrical form of the articulata, and the minute dimensions of the setæ, render them (with such a limited basis of support) very liable to turn upon their axis, and roll over on their backs, but they readily recover the pendent position of the abdomen by bending the trunk forwards into an arch, with its convexity resting on the plane of motion, and the head and anus raised above it, but inclined to one side: the inclined direction of the raised segments causes the animal to revolve on its axis, and regain its natural position.

When irritated, the Lumbrici contract and contort the body into curves resembling in form the letter S; they appear capable of contracting the body to one half of its entire length; in which condition the integuments present a corrugated appearance. The Nais and Naiades are swimmers. The Hæmocharis walks like the caterpillar of the Geometra. The Hirudines, or Leeches, are more developed in a transverse direction than the Lumbrici; in these animals the mouth is surrounded by a lip, and the anal extremity is furnished with a flattened disc, each of which is capable of causing a vacuum, and the head and anus being fixed to the plane of position, whilst the body is elongated and contracted alternately, the locomotion is effected. Leeches are well known to be capable of thus ascending vertically upon the smooth surface of glass, to which they adhere with considerable force.

Insecta. Apode larvæ of Insects.—The number of segments which compose the lengthened cylindrical form of the Apode larvæ and the disposition of the muscular system permit the trunk to be moved in various directions; to be elongated, contracted, curved upwards, downwards, or on either side, thus contributing to the progression of the Apodes. The cephalic, thoracic, and abdominal sections, which may be considered as merely auxiliary organs in animals furnished with arms and legs, are employed by the cylindrical Apodes as the sole instruments of locomotion.

The progression of the Balaneus Nucium, the Maggot of the hazel-nut, is thus performed. Having first laid hold, with the mouth, of some point in the plane of position, the body is contracted and curved upon itself, and the anal extremity drawn forwards; the latter then takes a fixed point for a fulcrum, and the segments which had previously approximated during the contraction, are again separated in succession from behind forwards, causing a slight undulation of the body in successive curves, vertical to the plane of motion. The head having been projected forwards by the elongation of the trunk, repeats the same actions, recurring as before, in succession. Their progression is slow and laborious, each step not being more than from one-twelfth to one-fourteenth of an inch. The Cionus Scrofulariæ, like the common Snail, secretes a slimy substance which enables it to walk on the leaves of the figwort, on which it feeds.* The larvæ of the Muscidæ are provided with unguiform mandibles, with which they maintain a firm hold, whilst the body is contracted and dragged forwards. Other larvæ, as the Syrphus, use their mandibles for the same purpose.†

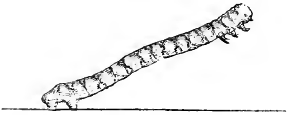
Pedate Larvæ.—Many of the pedate larvæ of insects are furnished with six legs like the

* De Geer, vol. v. p. 210.
† Kirby and Spence, vol. ii. p. 272.

perfect insect, which support the three first rings of the trunk. In many larvæ there are no organs of locomotion, whilst others are furnished with a variable number of rudimental legs, presenting differently constituted organs for progression. Most of the larvæ of the Lepidoptera have ten pair of these pro-legs, respectively articulated to the sixth, seventh, eighth, ninth, and anal segments of the body. One family, the Lophyrus, has sixteen pro-legs. Others, as the Stylotoma, have fourteen, and the Tenthredo twelve. The perfect legs move (according to Kirby and Spence) in the same order as in the imago state; the pro-legs serve not only to raise and support the abdominal and caudal segments of the trunk, but also to assist in grasping objects in the plane of motion, and in urging the centre of gravity forwards.

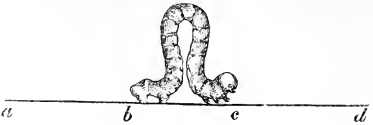
When the head and thoracic segments are fixed, the body and tail are drawn forwards; the trunk is arched in the vertical plane; the tail being fixed, the pro-legs are advanced successively in pairs, beginning from the anal segment; the body is then extended, and the head advanced to take a new position; a conspicuous undulation of the body is produced, proceeding from the caudal to the cephalic segments. The larva of the Ant-lion (Myrmeleon) moves in a backward direction, even after the removal of its legs. Many larvæ, such as the Caterpillar of the Hawk-moth, move with extreme slowness, whilst others possess considerable powers of locomotion, as the Apotela Leporina, which has received its appellation from the rapidity of its movements. But of all terrestrial larvæ, the most remarkable for their attitudes and motions are the Geometræ. The true Geometræ have only two anal, and two intermediate pro-legs; with these they grasp any object so as to fix the anal extremity: the trunk, with the head, is then extended, elevated, and inclined from the horizontal towards the vertical position, and the animal appears to be in the act of surveying surrounding objects as represented in *fig.* 233. In progression, the head being

Fig. 233.



fixed on the surface of motion at *c* (*fig.* 234); the anal extremity is drawn forwards to the thoracic segments, from *a* to *b*; the trunk is then again extended to *d*, and a series of the same alternate flexions and extensions is employed to carry the larva onwards. During progression, the Geometræ spin a silken cord, which they fix by the head on the plane of position at each step, thus measuring the distance over which they pass. The use of this cord is to enable them to descend from the

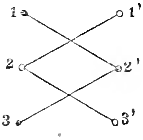
Fig. 234.



trees, however lofty, on which they feed, and to reascend by the same means, without the necessity of taking a circuitous route, and encountering the inequalities of the trunk and branches. In like manner the Caterpillars of the Cabbage-butterfly weave a ladder of silk on the plane of a glass-window, which serves as a fulcrum for its legs, and thus enables the animal to ascend.

Perfect Insects.—The order in which the legs of the Hexapods move in walking or running has been accurately explained by Professor Müller. Whilst watching insects which move slowly, he observed that three of their legs were always moving at the same time; these were advanced and put to the ground, whilst the other three propelled the body of the insect forwards. The feet, which moved simultaneously, were the fore and hindmost foot on one side, and the middle foot of the opposite side; then the fore and hind foot on this side, and the middle one of the other side, so that in two steps all the six feet are set in motion.* In the first movement, whilst the legs, 1, 2′, 3, (*fig.* 235)

Fig. 235.



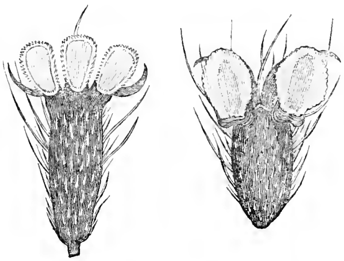
remain on some solid to support the body, and project it forwards, the other three legs, 1,′ 2, 3′, are raised and advanced; then, whilst the legs, 1′, 2, 3′ are, in their turn, supporting the body, 1, 2′, 3 are raised and advanced, and so on alternately. It will be observed, that the base of support in these movements is a triangular plane, with the three feet placed on the three angles; the base and apex of the triangle alternating at each alternate movement of each set of legs; so that in the first movement, the apex, which is at 2, takes the opposite side at 2′ in the second step. The Hexapods are supported by their three pairs of legs, and the stability of the animal is increased by the horizontal direction of the legs outward, this arrangement affording a larger base for the support of the centre of gravity. The first pair of legs being articulated to the prothorax, the second pair to the mesothorax, and the third to the metathorax, also gives to the longest axis an increased stability. The articulation of

* Müller, by Dr. Baly, p. 970.

the coxæ to the trunk is by cotyloid joints, as in the Rhimophoræ, or by ginglymoid joints, as in the Lamellicornes; and between the trochanter and femur, the coxa and trochanter, the femur and tibia, the joints are usually ginglymoid: the axis of each of these joints is turned at right angles to the next, so that, as Dr. Roget remarks,* "there results from the combination of both, a capability in the thigh of executing a circular motion, in a manner almost as perfect as if it had revolved in a spherical socket. The principle of this compound motion is the same as that employed on ship-board for the mariner's compass and other instruments which require to be kept steady during the motion of the ship. For this purpose, what are called *gimbals* are used, the parts of which have two axes of rotation at right angles to each other, so as to enable the compass to take its proper horizontal position, whatever may be the inclination of the ship." The remaining joints of the legs of insects are also ginglymoid. The tarsi, which vary in number from two to six, terminate by a double hook; those on the anterior pair of legs are directed backwards; those on the middle pair inwards; and those on the tail-piece, forwards; by which disposition the insect is enabled to lay hold of rough surfaces, and to walk up inclined or vertical planes with security.

In the progression of insects, the fore and middle legs are extended, and the hind legs flexed previously to urging the body forwards; in doing which, the actions of these legs are reversed. The simple hook terminating the locomotive organs of most insects will not enable them to walk on water, to climb vertically on glass, or stand inverted on ceilings, actions which many can perform, and for this purpose an additional apparatus is therefore provided. The common Gnat and some Coleopteræ which walk on the surface of water, have the tarsi furnished with a brush of fine hairs, which appear, when the surfaces are free from moisture, to repel the fluid with sufficient force to sustain the weight of the animal, and in confirmation of this theory, it is found that if the legs are moistened with spirit of wine, the animal immediately sinks and is drowned. Those insects which ascend vertically on the surface of glass, or remain suspended in an inverted position from the ceiling, are furnished with an additional apparatus. We have a familiar example in the House-fly, which has the extremities of its feet furnished with two funnel-shaped membranous suckers, moveable by muscles in every direction, by which they are capable of exhausting the air on very smooth surfaces, thus causing the pressure of the atmosphere to sustain the weight of the body: the area of these suckers is so beautifully adjusted to the weight of the insect, that the pressure of the air alone is more than sufficient to sustain the weight of the insect without exertion, and to suspend its body to a ceiling in an inverted position. The centre of gravity is is thus suspended, instead of being supported, the legs having merely to resist the force of gravity upon the body. In the Bluebottle-fly (*Musca Vomitoria*) these suckers are conspicuous, and the edges being serrated enable them to apply the disc of this pneumatic apparatus to any kind of surface. In the

Fig. 236. *Fig.* 237.



Bibio febrilis (*fig.* 236), the foot is furnished with three suckers, in the Musca domestica with two (*fig.* 237), and in the Cymbex Lutea with five. Numerous other species, amongst which is the common Wasp, are furnished with cushions and analogous suckers, which enable them to ascend vertically on glass.

The predaceous insects run with great velocity in proportion to their height. Those which are furnished with very short legs must advance them at intervals of time corresponding to the square roots of their length, on the supposition that their legs are subject to the same physical laws as those of the human race. Mr. Delisle observed a minute fly run three inches in half a second, making 540 steps in the same time; each of these steps must have been consequently $\frac{3}{540} = 0.0056$ of an inch in length. The great number of steps taken by these minute animals conveys to the mind of the observer an impression that the animal is running, whereas it is merely walking, the body not swinging freely in the air, as is necessary, according to the definition of Weber, to constitute the act of running.

Myriapoda.—In the Myriapods, the great number of legs and the celerity of their movements, as for example, in the Scolopendra, render it difficult to detect the order of their motions. The numerous segments entering into the lengthened form of the trunk, each of which is furnished with a pair of legs, give to the body great flexibility, and enable the Myriapods to turn from a right line to any curved or angular path, or to pass over rough surfaces with facility. The legs, in number from fourteen to forty-two, are short, and directed laterally; they are composed of four segments; all the joints, except that by which they are attached to the trunk, are ginglymoid, and terminate in a sharp conical claw, which gives precision and security in climbing. The legs appear to move in a determinate order; every

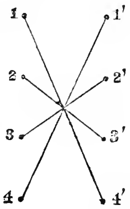
* Bridgewater Treatise, i. 294.

alternate leg on one side supports the animal, and urges the centre of gravity forwards, whilst the corresponding leg on the other side is raised and advanced to take a new position on the plane of motion. Such, at least, seems to be the process employed, but there is very great difficulty in ascertaining their motions with perfect accuracy; we therefore give the above in part practically, and in part hypothetically. The Myriapods move with considerable agility; usually run, and if disturbed, continue that pace for a great length of time. They have the power of climbing with facility the perpendicular surfaces of trees, walls, &c.

Arachnida.—The Arachnida are furnished with four pairs of legs, which render their mode of progression more complex, and more difficult of observation, than that of the Decapods.* Their coxæ are articulated to the base of the cephalo-thorax by cotyloid joints arranged in an elliptical form, and directed horizontally outwards; all the remaining articulations of the legs are ginglymoid, which is the best mode of articulation for the horizontal movements of the leg whilst urging the body forwards; the tarsi, which are composed of a variable number of segments, terminate by a double or single hook, which affords to this tribe of animals the means of ascending vertically, whenever any surfaces present minute irregularities adapted for prehension; the legs, projecting from the cephalo-thorax horizontally, increase the base of support. The centre of gravity is that of an ellipse. The Arachnida cannot ascend vertically on glass, but are enabled to walk in an inverted position on ceilings or rough surfaces without the assistance of their web.

The organs of motion in spiders, though nearly constant in number, differ exceedingly in length; the general principle is, however, the same. After long and repeated observation, I discovered the order in which the eight legs of these animals are put in motion. If we first attend to the manner in which the legs are moved on either side singly, they will be found to move first the fore leg, then the fourth, then the third, and lastly, the second leg; that is, in the order 1, 4, 3, 2. On observing the motion of the legs on both sides of the animal simultaneously, they are found to move the first right leg, then the fourth left; then the first left and the fourth right; then the third right and the second left; and lastly, the third left and the second right (*fig.* 238).

Fig. 238.



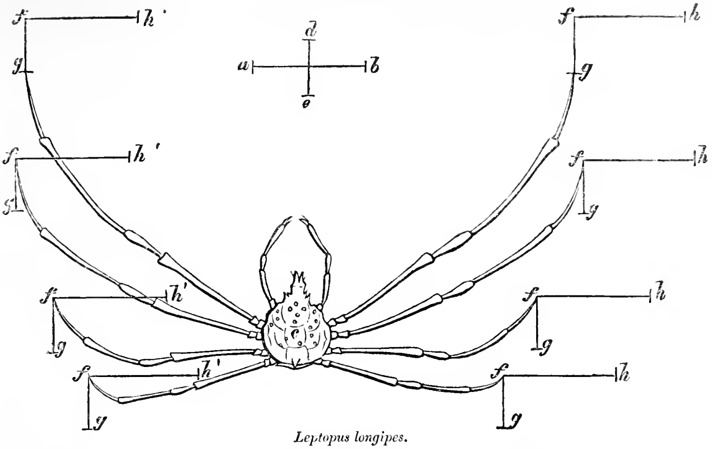
Of these, the first two sets are moved consecutively, like those of a quadruped, 1', 4, 1, 4'; the last two in pairs simultaneously, that is, 3', 2, then 3, 2'; and whilst the legs of one side of the animal are moving consecutively in the order 1, 4, 3, 2, the legs of the other side are moving in pairs in the inverted order 4', 1', 2', 3'. In descending vertically by means of a newly-spun thread, they hang by one of the hind legs; on ascending the same thread they employ three legs; the two first on one side, and the first or second on the other; in running, the second pair of legs is placed in advance of the first, then those of the third before the second, thus giving the feet a greater range of space at each step. The fourth pair, or hind legs, are directed backwards nearly parallel to the line on which the animal is moving; they seem to be chiefly used to support the posterior segments of the abdomen, but also exercise a limited action in propelling the body forwards. Four legs support the body almost, but not quite, simultaneously, as stated by Professor Müller, whilst the other four are raised. The progression of the spider is usually rapid; it can run upon its web with great facility; it can leap many times its own length in chace of prey; it can float during a limited period on water; and the facility with which it can spin and throw a cord across cavities from one fixed point to another, at a considerable distance, endows it with a mode of transit across spaces which is denied to many other animals.

Decapoda.—The modes of progression employed by the Decapods are both various and singular. Organized either to swim in rivers or seas, to walk and run on the dry land or at the bottom of water, both fresh and salt, they are furnished with organs of locomotion suitable for these different purposes. The five pairs of legs articulated at the base of the cephalo-thorax have the whole of the joints articulated, and directed to move on solids either laterally or directly backwards. The front legs are generally the most massive and powerful, throwing the centre of gravity forwards nearly between the axes of their articulations.

The Brachyurous Decapods, as the *Cancer*, *Maia*, *&c.*, present either a quadrilateral or a pyriform figure. They are generally destitute of the great elongations of the abdominal segments and expansion of tail into fins for swimming, which we find in the Macrourous Decapods. The consolidated carapace of the decapod tribe deprives them of lateral flexibility in the thoracic section of the trunk. The land species of Decapods, such as the *Cancer cursus*, or land crabs, are capable of running with such velocity, that a man on horseback has difficulty in keeping up with them. From their speed they were called by the more ancient naturalists *equi*. In many species, such as the *Inachus thoracicus*, the *Leptopus longipes*, and the *Leptopodia sagittaria*, the legs are greatly elongated, and consequently exercise a locomotive office resembling that of the tipula amongst insects, differing however from it in the direction of the articulations, by which the progression of these different classes is reversed. Thus in the *Leptopus longipes* (*fig.* 239), the action resulting from the flexion and extension of the legs in $g\,f$, $g'\,f'$ will propel

* The female is furnished with an additional pair, to enable her to carry her eggs.

Fig. 239.



Leptopus longipes.

the centre of gravity c backwards in the direction of $d\,e$, but by the elongation of one set of legs from f to h, and subsequent retraction towards f, and the simultaneous contraction of the other set from f'' to h', and subsequent extension towards f'', the centre c will be propelled laterally in the direction of $a\,b$, perpendicular to $d\,e$. The lines $a\,b$, $d\,e$ represent both the magnitude and direction resulting from the two movements of the legs, in $g\,f$, $g'\,f'$ and $h\,f$, $h'\,f'$ respectively, but, by changing the position of the legs, they may also move obliquely.

The Macrourous Decapods, as the lobsters, are all organized for swimming; and they have accordingly been considered under that section.

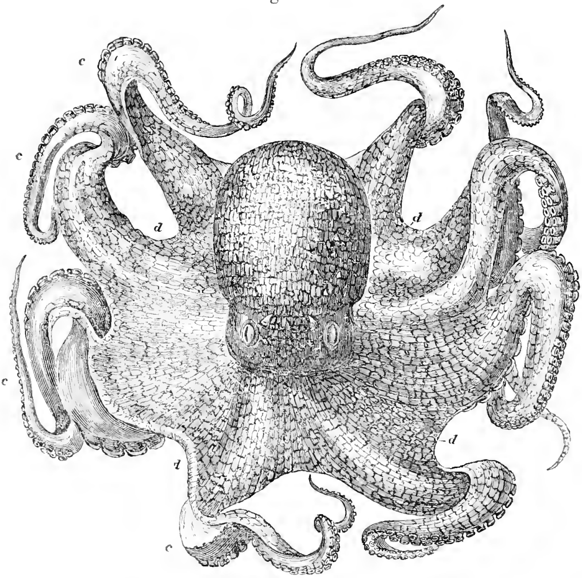
Gasteropoda.—The motions of the Gasteropoda are proverbially slow; the situation and structure of the muscular foot enable them to traverse surfaces vertically, as well as horizontally. The centre of gravity is supported within the base formed by the disc of the foot, which is organised to expand, contract, and curve in every direction; also to produce a vacuum, and to secrete an adhesive fluid for the purpose of securing the stability of their position on surfaces directed at any degree of obliquity, or on the ceilings of rooms, or roofs of buildings, in opposition to the force of gravity.

The *Limaces*, or slugs, and *Helices*, snails, present in progression a crawling or gliding motion. When, for instance, the *Helix pomatia* prepares for moving, the head, neck, and foot are first protruded from the shell; the foot is next extended on the plane of position, with the shell raised upon it; the muscular fibres of the foot then produce an alternate contraction and elongation of the successive segments of its disc, commencing posteriorly and proceeding forwards by a visible undulatory motion. During these alternate elongations and contractions, the animal glides perceptibly from point to point, though so slowly that many hours are required to traverse the distance of a few feet. As these animals crawl up the vertical planes of a glass window, the successive undulations of the foot are plainly visible when viewed from the opposite side. Müller considers them capable of producing a vacuum at various portions of the disc of the foot, thus availing themselves of atmospheric pressure in addition to their adhesive mucilaginous secretions. The patella, or limpet, and similar Gasteropods are well known to produce between the foot and plane of motion, a vacuum so powerful that the shell may be broken rather than the animal will suffer itself to be detached from the surface to which it adheres. The minute dimensions of each undulation of the foot render the Gasteropods incapable of traversing loose ashes or sawdust placed in their path, and these means are consequently often employed by gardeners to prevent slugs from destroying the young and tender plants.

Cephalopoda.—The locomotive organs of the Cephalopodous Molluscs are adapted to serve the triple purpose of legs for terrestrial progression, arms for prehension, and oars for swimming; the *Loligo* and *Sepia* are also furnished with fins, which are placed on each side the dorsal aspect of the trunk, and are the organs chiefly employed when swimming. Their terrestrial progression is performed by eight legs, leaving the two long tentaculæ free for prehension. The fleshy legs of the Cephalopods are extremely flexible, of various lengths, and capable of moving in every direction, whilst the acetabulæ enable them to lay hold of bodies with great force. In walking, the head and trunk are inverted, the direction of motion is retrograde, and they move very slowly on solids (*fig.* 240).

Ophidia.—The Ophidian Reptiles are destitute of organs capable of supporting and carrying the trunk in progression, and therefore they require some organs modified to render them capable of reptation. For this purpose we find the spinal column is composed of a greater number of vertebræ than is to be found in any other class of animals. The number of vertebræ varies in different species of Ophidia. In a large Python three vertebræ in their normal positions measured one inch, which in an animal of six feet in length would give 216 vertebræ of equal dimensions; towards the tail, however, their bulk diminishes, by which the flexibility of that part is augmented; the vertebræ are most numerous in some of the smaller species of Ophidian Reptiles. The bodies of the vertebræ are short, and are articulated together by a ball and socket joint which is situated at the inferior border of the body of the vertebra; but as this kind of articulation permits of a rotatory motion in every direction, it would render the whole spine exceedingly weak if the motion of the vertebræ was not restricted in some other part; to attain this object, and to give steadiness and precision in their movements, the articulating processes are elongated and furnished with double articular surfaces; of these the inferior is horizontal, and the superior oblique. The horizontal articular surface of one vertebra projects backwards as far as the extreme convex head of the ball, whilst that of the next vertebra projects forward as far as the edge of the socket; by this arrangement the horizontal articular surfaces are in contact to the extent of the depth of the socket. The superior oblique articular surfaces of corresponding portions of the two vertebræ are also locked into each other when the vertebral column is extended; all the articulating processes being cuneiform and fitting into cavities or upon corresponding surfaces effectually prevents any twisting of the body around it. The areas of the planes of the articular surfaces are sufficiently extensive to enable the animal to rotate each vertebra laterally 15° without causing them to slide from each other, consequently six successive vertebræ allow of a sufficient range of motion to render the animals capable of turning certain portions of its body at right angles to each other. Owing to the position of the arthrodial joint, a small amount of flexion on the abdominal aspect in the mesial plane is sufficient to produce a considerable space between the spinous processes, so that the motion of the spine in this direction is rather restricted, and from the same cause the spine cannot be but very slightly flexed on the dorsal aspect in the mesial plane without dislocation. The movements of the spine for the purposes of locomotion are, therefore, chiefly lateral. The ribs which extend from the atlas to the anus are articulated to the short transverse processes of the vertebræ, and in consequence of the absence of the sternum, scapula and pelvis, are endowed with great freedom of motion; they act in pairs on the transverse abdominal

Fig. 240.



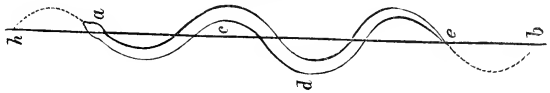
The *Octopus vulgaris* represented in the act of creeping on the shore, its back being turned towards the spectator, towards whom it is supposed to be advancing.

scuta (which take a variable number of fixed points in the surface of motion), and enable them to propel the body forwards and supply the place of so many legs. Their muscular system, though capable of exerting great power, acts at a mechanical disadvantage, and is quickly exhausted. Serpents move by different methods, and upon different principles of progression. First, in a straight line, with the whole ventral aspect of the trunk in contact with the plane of motion. Secondly, in a curved line, with the trunk arched laterally, and the ventral aspect also in contact with the ground. Thirdly, in a curved line, with the body moving by an undulatory alternate elongation and contraction of small segments of the body. Fourthly, in a straight or curved line, with the trunk arched vertically in two or more curves. Fifthly, in a straight or curved line, with the trunk arched vertically in a single curve, consisting of the greater part of the trunk. Serpents possess also the power of climbing, swimming, and springing. In the first order of locomotion, or that of a straight line, with the whole of the ventral aspect resting immediately on the ground, the serpent is urged onwards by the oscillation of the ribs acting on the abdominal scuta, at successive points of its length. The scuta of a segment or segments having secured a fulcrum in the plane of motion, the ribs connected with the fixed scuta, acting in turns, rotate backwards; the next segments in advance perform a similar action, until the whole series have completed the step. The length of the complete step depends on the arc through which the ribs oscillate, and the distances of the scuta from the axes of motion; and, as these are both small, and the motion has to be transmitted through the whole length of the reptile, this method of progression is, in consequence, very slow, presenting to the eye a tardy gliding movement.

In the second order of motion, the progression is performed in a curved line, with the ventral aspect also in contact with the ground. The method of advancing in this order is similar to that in the first; but as the reptile passes through a larger space in order to reach a given point, the progression will, consequently, be slower. Thus, if the reptile be flexed as represented in *fig.* 241, its length, when extended being equal to the right line *h b*, becomes by flexure only equal in the direction of motion to *a e*.

In the third order of motion, the reptile

Fig. 241.

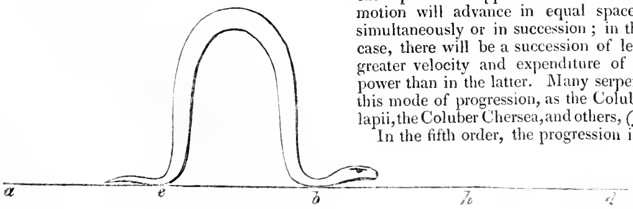


is curved laterally, as in the second, but small segments of the trunk are successively flexed and extended, and the steps taken do not depend on the time or extent of the oscillations of the ribs, but on those of the retractions and elongations of the segments of the body; and as the latter greatly exceed the former in celerity and amount, the progression in this order is vastly greater than in the preceding, which is the slowest. These modes of progression are practised by the common Snake, the collared Viper, and other Ophidians.

In the fourth order, the trunk is arched into three or four vertical curves. This is an accelerated mode of locomotion; first, the spaces taken at each step are large; and secondly, because the reptile moves in a straight line. When the head *b* is advanced from *b* to *h*,

Fig. 242.

Fig. 243.



each point of application to the plane of motion will advance in equal spaces, either simultaneously or in succession; in the former case, there will be a succession of leaps, with greater velocity and expenditure of muscular power than in the latter. Many serpents adopt this mode of progression, as the Coluber Esculapii, the Coluber Chersea, and others, (*fig.* 242.)

In the fifth order, the progression is effected by the flexion and elevation of the trunk in a single arc or curve, as seen in *fig.* 243. If during the extension of the reptile the tail be at *a*, it is by flexion advanced to *e*, during which motion the head is fixed at *b*; the tail being then fixed at *e*, the body is suddenly extended, and the head projected to *h*; so that in these two actions of flexion and extension the serpent has advanced through a space equal to *a e* or *b h*. The velocity of this mode is great, but will manifestly depend on the number and magnitude of steps taken in a given time. This mode of progression is that used by the rattlesnake, when the greatest speed is necessary in pursuit of prey, for instance, or in escaping from an enemy. When these flexions and extensions are performed with the greatest rapidity, the speed of the rattlesnake exceeds that of man. The principle of locomotion in the fifth order is similar to that of the larvæ of the Geometræ, and might, with equal propriety, bear the same designation.

The Amphisbæna walks with equal facility either backwards or forwards; the lower jaw being supported by the tympanic bone, which is articulated to the cranium, is used by these serpents as a fulcrum for retrograde progression. The Boa and the Python climb trees with great facility; this they effect in a spiral curve, the scuta of various segments, through their enormous length, laying hold of the bark; and aided by the great flexibility of their vertebral column, they are enabled to ascend in opposition to the force of gravity. They select trees in the vicinity of streams and rivers, and suspending themselves from the branches in an inverted position by means of their prehensile tail (which is furnished with a corneous hook on each side the anus), seize and crush quadrupeds even of large size as they approach to drink.

Serpents are also capable of darting, either from the curved position or the spiral coil, by the sudden elevation of the body to an erect posture; such is the movement of the deadly Cobra de Capello in its attack on the unconscious traveller, and in the same manner the common Viper inflicts its less dangerous wound. The erection of the trunk, either from the vertical curve of the Rattlesnake or the horizontal coil of the Cobra, is said to generate a projectile force sufficient to raise the reptile above the plane of motion. Although destitute of the limbs with which the higher vertebrata are furnished, serpents are endowed with the power of transporting themselves from place to place with a velocity greater than many bipeds and quadrupeds. Their locomotive powers enable them to chase and capture their prey; to stride across plains; to ascend and descend hills and precipices, inaccessible to most of the higher animals; to climb trees; to swim lakes, rivers, and seas; and thus not only to provide the means of subsistence, but also to choose those places of abode which are most suitable to their wants, pleasures, or habits.

Amphibia.—In consequence of the amphibious nature of many Batrachia their locomotive organs are adapted both to terrestrial and aquatic modes of progression. The carnivorous Caducibranchiates in an adult state present an almost quadrilateral figure, and as many of the osseous elements of the skeleton (which in fishes are separate) are anchylosed together, they give solidity to the framework, and afford levers and fulcra for muscular action to sustain the shocks necessarily connected with a terrestrial mode of locomotion. In the Frog the anterior extremities are short compared with the posterior; the toes are furnished with a broad web, consisting of an expansion of the integuments, a structure which, with the length and strength of the posterior extremities, renders them well adapted for leaping and swimming. The eight vertebræ have a ball and socket articulation, which gives them some degree of motion on each other. Their legs being directed horizontally prevent the Amphibia from supporting their trunks above the plane of position.

In a state of repose, the Frog assumes a sitting posture; the thighs are flexed forwards and outwards; the legs are flexed backwards on the thighs; the lengthened feet and toes are again directed forwards; the trunk is inclined to the vertical plane at an angle of about 45°, which brings the centre of gravity within the base formed by the pelvis and posterior extremities, leaving the anterior extremities either free or lightly touching the ground. The legs, in a state of flexion, are ready on the least alarm to project the body forward by their sudden extension.

The Bull-frog is said to project itself six or eight feet at each leap, and the leaps are repeated so rapidly that it is captured with difficulty, unless chased at a great distance from the water. It will also spring over a wall five feet in height. The Hyla, or Tree-frog, has each of its toes furnished with a concave disc, which acts as a sucker to enable the animal to attach itself to branches of trees, amongst which it runs with great facility. The feet of the Rana esculenta and Rana pipa are palmated for swimming, those of the Rana bufo semipalmated, and the Rana calomella and others have two osseous tubercles on the palms of the hands, which enable them to climb the planes of old walls in order to secrete themselves in the crevices.

The urodelous kinds of Caducibranchiates are adapted for land and water; those adapted for terrestrial progression have the tail of a cylindrical form, as in Salamandra, whilst those adapted for the water, as the Triton, have a pisciform tail, the planes of which are directed vertically.

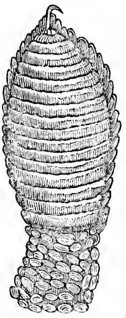
The perennibranchiate tribes of Amphibia residing constantly in the water, and with very rudimentary atlantal and sacral extremities, have the trunk elongated and pisciform, and the tail compressed laterally to give a greater impulse in swimming, as in the Proteus, the Axolotl, Siren, &c.

Saurian Reptiles.—The Sauria have commonly four legs, but a very few are restricted to two. Of these, some are organized for progression on land, others for locomotion both by land and water. The outline of the Sauria presents a lengthened form, having the atlanto-sacral axis much greater than the transverse; they partake more of the figure of the Ophidian than of the Chelonian reptiles, but differ from the former in having legs for the support of the trunk and for locomotion, and also in having a more complex skeleton, including besides the vertebral and costal bones, scapulæ, clavicles,* sternoid, pelvic, and sacral elements, as in mammiferous quadrupeds. The acetabula of the scapulæ and ossa ilii are inclined horizontally outwards; the humerus and femur, which are short, take the same direction; the ginglymoid articulations of the elbow and knee joints are inclined backwards eccentrically to those of the shoulder and thigh. The effect of this is that the extension and flexion of the fore-arm and leg, being made in the plane of the transverse horizontal section of the body, are at the same time movements of abduction and adduction; an arrangement which renders the extremities ill adapted for rapid progression on land. Those Sauria which have the four legs nearly of an equal length may be considered the best adapted for locomotion; the vertebral column being in this case parallel to the plane of motion. When the legs are nearly of equal length, the bones of the anterior and posterior extremities bear the following proportions: in the arm of the Crocodilus acutus the humerus is found to be 4.334, the ulna 3 083; and in the leg, the femur 4.666, the tibia 3.5 inches, so that $4.334 + 3.083 - 4.666 - 3.5 = -0.75$ inch for the difference of the length of these bones. The metatarsus and toes are longer and broader than the carpus and phalanges of the fingers, and present a large surface to strike the water in swimming.† The posterior extremities of the Biporcatus are palmated,‡ those of the Cayman semipalmated. The legs of the Sauria are very short compared with the length of the animal, (which, in the Biporcatus, is more than 10 feet,) and their horizontal inclination tends still more to depress the centre of gravity towards the plane of motion. From the same cause the legs act on land at a great mechanical disadvantage.

In the Crocodilean Sauria, the cervical vertebræ have but a limited lateral motion owing to the projection and interposition of the false ribs; the dorsal vertebræ have their transverse processes elongated and fixed to the ribs, which have no tubercles, consequently there is but little lateral motion of the back; the lengthened tail, however, admits of considerable lateral play and is of great use in swimming. The Crocodile cannot curve its trunk abruptly or turn it at an acute angle with facility; it runs, however, with considerable agility in a right line. The bones of the skeleton are of a fibrous spongy character, which diminishes the specific gravity of the animal, and is a great advantage in its swiftest mode of progression, which is in a fluid medium.

Lacertæ.—The Lacertine Saurians are smaller in dimensions than the Crocodilean, and possess much greater mobility of the vertebral column; the prolongation of the animal in the axis of its mesial section is much greater than in its transverse section. As in the Crocodilean species, most of the Lizards are provided with four legs, but a very few species have two only. In a few forms, such as the Chirotes and Bipes, the animal cannot support the body above the surface of motion, and consequently drags the thoracic and abdominal segments along upon the ground. In consequence of the construction of the hands, claws, and prehensile tail, many Lizards climb with facility. The Gecko is provided with a pneumatic apparatus which it employs in a manner similar to that of the house-fly; the under surface of each of the five toes, which (with the exception of the thumb) terminate in a sharp claw, is furnished both in the fore and hind feet with as many as sixteen transverse plicæ, which open into as many cavities or sacs (*fig.* 244). The contraction of the muscles, acting upon these plicæ and sacs, erects the former and dilates the cavities of the latter; the serrated edges being at the same time accurately applied to any smooth surface, a vacuum is produced, and by this structure the animal is enabled to climb up the vertical planes of walls, and to walk in an inverted position on the ceilings of rooms. The Anolis and Tupenambis, as well as the Gecko, run with considerable speed, and have the power of leaping a great distance; others propel themselves either backwards or forwards by applying two or more parts to the ground as a fulcrum, and by the alternate flexion and extension of the body, aided by the long and flexible tail.

Fig. 244.



In the *Thecadactylus* the toes are expanded and furnished at their lower extremities with transverse folds; these folds are divided by a deep longitudinal groove, in which the claw can be entirely concealed; by this provision the claws are preserved sharp for climbing.

In the *Ptyodactylus*, the toes are flattened into plates, the lower parts of which are striated like a fan; the middle of the fold is cleft, and the claw is fixed in the fissure. All the toes have the claws very much curved. This peculiar organization of the feet enables the animal to climb with great facility.

In order to allow of the more secure prehension of its insect food on the agitated branches of trees, the Cameleon has short, strong, muscular limbs; a strong, flexible, and prehensile tail; two thumbs opposite to three

* The Crocodile has no clavicle.
† Hunterian Museum.
‡ The same remarks apply generally to the Alligators of America as to the Crocodiles of the Old World.

fingers on the anterior extremity, and three thumbs opposite to two fingers on the posterior. Many of the climbing Lacertine Sauria have very elongated and flexible fingers, which give them great power of prehension and rapidity of motion, so that they are enabled to climb rapidly up the vertical surface of walls and trunks of trees.

Chelonia.—The Chelonian reptiles are enclosed in a ponderous case formed by the carapace and plastrum, which they are destined to drag along with them in all their movements. In the terrestrial species, the dorsal, costal, sternal, and pelvic osseous elements are all fixed, leaving the neck and caudal extremities of the body alone free. The legs, which are short and curved, act in consequence of their horizontal inclination at a great mechanical disadvantage, rendering the progression of the Chelonia proverbially slow. The humerus is bent, and in pronation is locked against the plastrum; the latter tends to assist it in supporting the animal. The same body also prevents the femur from exercising any great degree of flexion, but allows it more freedom of action in extension; from the relative position of the cotyloid articulation and the absence of that impediment in the direction of extension, the hinder extremities give altogether a more effective impulse in walking. The length of the arm and fore-arm equals that of the thigh and leg.

In the Testudo elephantopus, the femur measures five inches, the tibia five, the humerus six, the radius four; then as $5 + 5 = 6 + 4$, the sum of the lengths of the anterior and posterior extremities is equal. The feet and hands of the Turtle are furnished with a membranous expansion between the toes and fingers, which enables them to act as fins. The anterior extremities in this species are much more developed than the posterior. The body is remarkably flattened and depressed so as to present the smallest amount of resistance in cleaving the water in quest of their vegetable food. In the Emydes, or fresh-water Chelonia, the feet are palmated, by which means they are enabled to move with greater facility and expedition on soft and yielding surfaces, such as muddy banks and rivers, as well as to swim in pursuit of their prey in the water. The Chelonia are remarkable for the great transverse extension of the trunk compared with their length; they differ in their mode of progression from the Ophidian reptiles in having legs, and from the Saurians in the immobility of the ribs. The *Aquatic Chelonia* are rendered of less specific gravity than their bulk would indicate, both by the spongy texture of their organs of support and by the great extent of their respiratory apparatus, which reduce their specific gravity to that of the medium in which they move, and admit of their sleeping motionless on the surface of the water.

The structure of the arch-formed carapace and dense plastrum, and the more solid union of all the osseous elements surrounding the trunk of the *Terrestrial Chelonia*, enable them to resist the external pressure to which, from their partially burrowing habits, they are subjected, and also to endure the trampling of large quadrupeds.

Birds.—The feathered tribe traverse the surface of the earth as digitigrade bipeds. In standing, the trunk is elevated and supported at various heights above the plane of position, by the legs through which its weight is transmitted to the ground. It is balanced and kept in equilibrio on an axis passing through the centres of the heads of the femurs perpendicularly to the plane of the mesial section.

The inclination of the trunk lies between the vertical and horizontal planes; but its angle of elevation depends on the position and weight of its various elements and appendages, such as the head, neck, and anterior extremities, which determine the distance of the centre of gravity to the cotyloid articulation. The ilio-femoral articulations being placed more forwards in the ossa innominata than in quadrupeds, enables them to bring the centre of gravity within the base of support on their two feet with little elevation of the trunk. Several methods are employed by birds to alter the relative position of their centre of gravity in standing, namely, first, by curvature of the neck; secondly, by folding the wing on each side; thirdly, by the elevation or depression of the trunk above or below the horizontal plane in which the cotyloid joints are situated. All these different positions of the trunk and its appendages throw the centre of gravity backwards towards the vertical line passing through the base of support, which may also be changed and thrown forwards by bending the joints of the legs.

The areas of the bases of support vary in different orders of birds according to the number, length, and direction of their toes. The action of the gracilis muscle, which enables birds to stand on one leg in repose, was demonstrated by Borelli, and though his views were opposed by Vicq D'Azyr and Barthez, they have been confirmed by Monro, Cuvier, Müller, Roget, and Owen. In walking slowly, the body rests a long time on both legs and a short time on one; during the former period the motion of the trunk is retarded, but during the latter it is accelerated. In these movements, one leg is flexed, raised from the ground, and swung forwards to take a new position in advance, whilst the other supports the trunk and propels it forwards; and as soon as the foot of the raised leg arrives in a position perpendicular to the head of the femur, the hind leg is lifted and repeats the like movements. The time during which the body is supported on one leg, in proportion to that when it is resting on both, depends on the celerity of progression. The time of the oscillation of the swinging leg is governed by the length of the leg and the arc through which it is suffered to oscillate.* In walking, the centre of gravity oscillates laterally; this motion is

* For further details on walking upon two legs see those on human progression, many of which are applicable to birds.

most conspicuous in some of the Natatores, as the Goose, Duck, &c., and in those birds which have the greatest space between the cotyloid cavities and the least length of legs. Many birds depress and elevate the head, and extend and retract the neck at each step, in order to preserve in equilibrio the forces acting on the centre of gravity; the Moor-hen and some others are also observed to spread out the tail like a fan, which is alternately elevated and depressed at each step; and these successive actions of the tail taking place at the extremity of that portion of the lever opposite to the head, tend to produce an equilibrium between those portions of the trunk lying on each side of the cotyloid articulations.

In the progression of some of the long-legged Grallatores, such as the Crane and Stork, the swinging leg describes a portion of a circular curve round the standing leg. Pliny appears to have observed this kind of movement, for, in his Hist. Nat., lib. x. c. 23, he says, "Grues mansuefactæ gyros quosdam indecoro cursu peragunt."

A large number of birds, such as the Sparrows, Canaries, Blackbirds, &c., instead of moving the two feet alternately, move them simultaneously: in these movements the legs are first flexed and then suddenly extended in succession, by which means the trunk and both legs are elevated from the ground, and progression is effected by a series of short leaps. In running the Cursores outstrip all other birds, and perhaps all other animals. The osseous columns which support the trunk are of great length and size, and are acted on by powerful muscles. The femurs, though short, have a considerable diameter; the tibia is long, but still longer is the tarso-metatarsal bone. The bones of the legs elevate the trunk to a great height, by which they are enabled to stride over a large space at each step. Aided by its comparatively diminutive wings, the Ostrich will outstrip the fleetest Arabian horse in his flight across the desert, as will the Cassowary the swiftest Greyhound. Thus, though deprived by the comparative smallness of their wings of the power of aerial progression, these birds are fully compensated by the velocity of the terrestrial movements.

The Scansores, such as the Woodpecker, Parrot, Cuckoo, &c have the internal toes and thumbs turned backwards, which enables them, with the assistance of the tail, to climb and to suspend themselves to the upright trunks of trees; during which action, the legs, tail, and that portion of the tree against which they rest form the three sides of a triangle.

Mammiferous Quadrupeds.—The locomotive organs of the mammiferous quadrupeds are more highly organized than those of the Batrachia and Chelonia. The bones of the skeleton are more compact, hard, and dense, and contain a greater proportion of the calcareous phosphate; they are, therefore, better calculated to resist the shocks incidental to terrestrial progression: the vertebral column, which is directed horizontally, is convex at its dorsal and concave at its ventral aspect. It forms a single arch, extending from the pelvis to the last cervical vertebra, as it is kept bent by strong ligaments. It constitutes a powerful elastic column, well adapted to support the weight of the abdominal viscera as also of extraneous burdens which these animals are destined to bear. The spinal column of mammiferous quadrupeds is endowed with much greater mobility and elasticity than in the Saurian and Chelonian quadrupeds. The trunk is directed horizontally, resting on the four legs, which, like so many columns, support the centre of gravity. The scapulæ and pelvis have the power of rotating in a vertical plane through a large arc; the axes of the acetabula of the shoulder and hip-joints are directed vertically downwards to receive the heads of the ossa humeri and femoris, the shafts of which are directed vertically upwards. These ball-and-socket joints permit the several motions of flexion and extension, abduction and adduction, pronation and supination: the rest of the joints of each extremity are ginglymoid, a construction which, although it restricts the limbs thus articulated to movements in one plane, yet secures to these movements greater precision. The joints are lined and lubricated by synovial membranes, which, throughout the life of the animal, effectually secure them from injurious friction notwithstanding their varied and long-continued exertions. The elastic ligaments permit great freedom of action under all ordinary circumstances without rupture. The osseous columns, which enter into the composition of the extremities, are piled upon each other endways, with their long axes either vertical or inclined; and, in order to give them the power of sustaining the greatest possible pressure with the least weight and expenditure of solid materials, the shafts of the long bones are formed into hollow cylinders, of which the height and base are adjusted to each other with the greatest mechanical precision. The bones of the extremities in most mammiferous quadrupeds are inclined to each other's axes at a greater or less angle, the magnitude of which is in proportion to the bulk and speed of the animal. In those quadrupeds which have the greatest bulk and least velocity of locomotion, the bones approach nearest the vertical direction: such is the case with the elephant. On the contrary, in those animals which are remarkable for the greatest speed, the axes of the bones are inclined to each other at the greatest angle.

Although the angular disposition of the bones diminishes their power of sustaining great weight, and increases the expenditure of muscular effort, yet it confers on the legs greater elasticity, and enables them, from the oblique transmission of the impulse, to sustain sudden shocks without fracture of the bones; it also enlarges the range of motion, and gives the posterior extremities greater power of projecting the body forwards during rapid locomotion. The bones of the anterior extremity having to support the weight of the head and neck, as well as a large proportion of the trunk, are inclined nearer to a vertical direction than those of the posterior; this tends to throw the centre of gravity a little in advance of the middle of the quadrilateral figure described by the four legs of the quadruped on the plane of position.

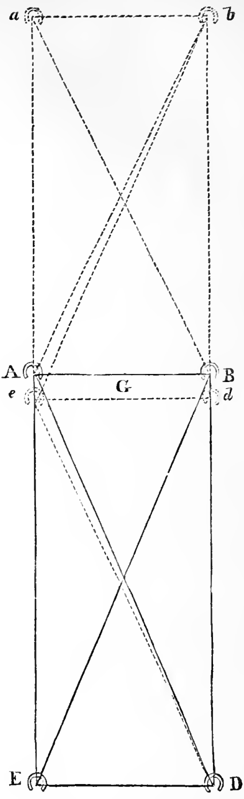
Although the bones of the posterior extremities are inclined to each other at a greater obliquity than those of the anterior, they have the calcaneum projecting considerably beyond the axis of the calcaneo-tibial articulation, so that, acting with the advantage of a powerful lever, the waste of muscular force is diminished, and the disadvantage arising from their obliquity is partially compensated. The time and order in which the legs of quadrupeds succeed each other in motion determine the paces denominated the walk, the trot, the gallop, the amble, and the leap, or bound.

In order to illustrate many of the general principles on which the progression of quadrupeds is effected, we shall select the horse as an example. In standing, the animal rests its trunk on the legs which form the four columns of support. Let us suppose the legs to be placed on the ground at A B E D (*fig.* 245): if these points be joined, they form a rectangular parallelogram.

When the animal walks slowly with his right side in advance, the left hind leg moves first; the right fore leg second; the right hind leg third; and the left fore leg fourth. During these four successive motions, the centre of gravity is propelled forwards over a space equal to the length of one step. Let us now investigate what takes place during these successive motions. The hind foot having been previously extended, and having urged the centre of gravity forward, is first moved; it is then flexed, lifted from the ground, and advanced from E to *e*. Whilst the leg E is in the act of advancing to *e*, the trunk is supported on three legs, A B D, thus having the base of support transferred from the plane of a rectangular parallellogram to that of a right-angled triangle.

In this movement, the centre of gravity G must fall within the plane A B D, which is effected by an oblique lateral movoment of the trunk towards B D. The foot E having taken a new position at *e*, the second foot B is set in motion, raised, and advanced to *b*, and the base of support becomes transferred from the rectangular triangle, A B D, to the oblique-angled triangle, A *e* D: by an oblique lateral motion of the trunk, the centre of gravity is propelled towards A *a*, within the new base of support, leaving the leg free to move without danger of the horse falling. The leg B having advanced and taken a new position at *b*, the leg D is next raised and advanced to *d*, during which the base of support is transferred from the plane A *e* D, to that of A *b* *e*, within which the centre of gravity is propelled; lastly, the leg A is advanced to *a*, and the base of support is transferred from the plane A *b* *e* to that of *b* *e* *d*. When the leg A has reached the point *a*, the base of support becomes a new parallelogram *a* *b* *e* *d*, equal in dimensions to that of A B E D. In walking, the four legs move in the order above-mentioned successively. The time occupied in performing the series of movements to complete a step varies. In horses of large dimensions, one foot moves the length of a step every second, and, therefore, each leg swings one quarter, and rests on the ground three-quarters of a second. In walking at a more rapid pace each leg moves in rather a less period, and the interval between the setting down of one leg and the rising of the next vanishes.

Fig. 245.



The trot.—In the trot the legs move in pairs diagonally. If the legs A D (*fig.* 246) be first raised and advanced, then B E will generally be raised the instant that A D reach the ground; on the other hand, when the legs B E are raised before those of A D reach the ground, the trot approximates to the gallop of two beats, the four legs being at the same time, for a minute interval, above the plane of motion. The bases of support in the trot are the lines A D and B E alternately. The same

Fig. 246.

leg moves rather oftener during the same period in trotting than in walking, or as 6 to 5. The velocity acquired by moving the legs in pairs, instead of consecutively, depends on the circumstance that in the trot each leg rests on the ground during a short interval, and swings during a long one, whilst in walking each leg swings a short, and rests a long period. The undulations arising from the projection of the trunk in the trot are chiefly in the vertical plane; in the walk they are in the horizontal.

In fig. 246, as designed by Bewick, and adapted to our purpose, we observe that the vertical line passing through the base of support, lies not only behind the centre of gravity of the horse, but also of the centre of the mass of the rider, consequently the anterior legs will bear much the greatest proportion of the burthen.

The gallop.—The gallop may be divided into three kinds, which may be distinguished by the number and order in which the feet happen to reach the ground. When the horse begins the gallop on the right, the left hind leg reaches the ground first; the right hind and left fore legs next, simultaneously, and the right fore leg last; this is termed the *gallop of three beats.* In the gallop where the four legs strike the ground successively, the left hind foot reaches the ground first, the right hind foot second, the left fore foot third, and the right fore foot fourth; *this is the gallop of four beats*, but it is not the kind of movement adapted for great speed.* The gallop wherein the legs follow the same order as in the trot,—that is, the left hind and right fore feet reach the ground simultaneously, then the right hind and left fore feet;—is the order in which horses move their feet in racing, where their greatest speed is required, and is called the *gallop of two beats.*† In the *amble*, the two legs on one side rest on the ground, and propel the centre of gravity forwards, whilst those on the opposite side are raised and advanced, and on taking a new position on the plane of motion, the former pair are raised and advanced in a similar manner: these successive actions are accompanied by a considerable lateral motion. The amble is the pace peculiar to the Giraffe: in the horse it is only effected by artificial training. Borelli has erroneously described the order of the motions of the feet of the horse in walking; he states that the fore and hind feet on the same side move first, and then the fore and hind feet on the opposite side: these views, however, differ from the order as described by Aristotle,* and they have since been opposed by Barthez and Müller, whose opinions coincide with those which, after repeated observations, have been here introduced. In the gallop, the centre of gravity moves in a vertical plane, and describes the path of a projectile. The space passed over on the plane of motion is equal to the horizontal velocity of the centre of gravity multiplied by the time.† According to Sainbell, the celebrated horse, Eclipse, when galloping at liberty, and with its greatest speed, passed over the space of twenty-five feet at each stride or leap, which he repeated $2\frac{1}{3}$ times in a second, being nearly four miles in six minutes and two seconds. The race-horse, Flying Childers, was computed to have passed over eighty-two feet and a half in a second, or nearly a mile in a minute. Sainbell has given the geometrical proportions of Eclipse, together with the angles of inclination and range of motion of the joints of the four extremities. He states that a considerable angle of inclination of the shoulder-joint, as well as an angular disposition of the limbs, are essentially necessary for great speed. Sir C. Bell,‡ however, states, "that the speed of a horse depends on the *strength of his loins and hind-quarters*, and what is required in the fore-legs is strength in the extensor tendons;" but surely this hypothesis cannot be correct, or the brewer's dray-horse would be the fleetest. The horse is one of the most useful and most perfectly organized quadrupeds, combining great strength with speed. The length, strength, and angular disposition of the bones of the legs, the power of the muscles, the structure of the joints, the lengthened metatarsal and metacarpal bones, the consolidation of the phalanges, and the structure of the expanded foot, all conspire to perfect the geometrical proportions of this valuable quadruped.

Having now given in detail the various movements of the horse, we shall briefly pass to the other orders of Mammalia.

Marsupialia.—In the Kangaroo, we observe a greater disproportion between the length of the anterior and posterior extremities than is found in any other quadruped, the length of the legs to that of the arms being as $38\frac{1}{2}$ to $17\frac{1}{2}$ inches,§ or rather more than two to one. This

* The gallop of four beats is often denominated "*the Canter.*"

† See Sainbell.

* After the right of the fore feet they move the left of the hind feet. Afterwards they move the left of the fore feet and right of the hind feet. *See Taylor's Aristotle on the Progressive Motion of Animals*, chap. xiv.

† See eq. 1.

‡ Library of Useful Knowledge, Art. Animal Mechanics.

§ These measures are taken from a skeleton in the Hunterian Museum. Some variation will occur in the absolute length of the extremities, arising from the age and magnitude of the animal; but the ratio of the length of the extremities in the difference arises chiefly from the great length of the tibia, which is nearly equal to that in the Giraffe, the former being to the latter as 16·5 to 18 inches. In the *Rodentia*, as the Hare, Agouti, and Guinea-pig, we observe a similar disproportion in the length of the extremities. The Rabbit, in moving slowly, advances the anterior feet two or three steps alternately, the posterior limbs remaining inactive. The body having been elongated by this means, the posterior legs are suddenly extended and drawn forwards simultaneously; thus, the rabbit walks with the fore, and leaps with the hinder pair of legs. Those quadrupeds in which the length of the posterior extremities much predominates over that of the anterior, are observed to descend declivities in a straight line with difficulty, on account of the great inclination of the axis of the trunk to the plane of motion, which puts the animal in constant danger of oversetting; they therefore take a zigzag course. In ascending a hill, however, their progression is greatly facilitated by the length of their posterior extremities. The speed of the Hare is well known to be greater than that of the fleetest horse or hound.

Ruminantia.— Many of the Ruminantia, such as the Deer and Antelope, are beautifully and symmetrically organized for rapidity of locomotion; the Camel for prolonged power of traversing the arid desert; and the Ox for the strength and development of its muscular system.

Amongst the Ruminantia some species have the neck of great length, and the head being surmounted with massive horns, or antlers, renders it necessary that the spinous processes of the lower cervical and superior dorsal vertebræ be lengthened, so as to form powerful levers for the attachment of muscles, and of that yellow elastic tissue, the *ligamentum nuchæ*, which is greatly developed in the Ruminantia, to support the head and its appendages; the latter acting at the end of a long lever tends to throw the centre of gravity forwards nearly between the anterior extremities. The figure of the trunk is elliptical; its transverse axis diminishes as it approaches the anterior extremities; there are no clavicles; and from the small degree of curvature of the ribs, the arms are thrown almost together beneath the trunk, and nearly in the plane of the mesial section of the body. The Giraffe presents greater length of osseous columns for the support of its superstructure than is to be found in any other animal; the bones of the anterior extremity are directed more vertically than those of the posterior, which enable it to support, with less weight of bone and less expenditure of muscular force, its lengthened neck, upon which the head acts as at the end of a long lever. The metatarsal and metacarpal bones are of great length, and being directed vertically, as in the Pachydermata, the trunk is elevated to a great height. The three phalanges of each finger and toe are inclined forwards; the extensor tendons act on them by means of a pulley, through the interposition of the sesamoid bones, which increase the distance of the direction of the tendons from the axes of the joints, and give them greater power.

The length of the arms to that of the legs in the Giraffe is as 71 to 67 inches, which gives a difference of four inches in favour of the length of the arms. This disproportion is further augmented by the lengthened scapulæ, and by the increased angular disposition of the posterior extremities.

In the Camel, the length of the legs is more nearly equal than in the Giraffe, the anterior being to the posterior limbs as 49 to 47 inches; the spine is consequently directed more horizontally than in the Giraffe. The order in which the movements of the legs succeed each other in the Camel is like that of other quadrupeds. The velocity of the camel at its common travelling pace is estimated at $2\frac{1}{2}$ miles an hour.*

In Deer and Antelopes, the geometrical proportions are such as to confer on them great speed. The lightness, elegance, and strength of their osseous fabric, the energy of their muscular system, the freedom of motion in the vertebral column, the large arc described in the greatest rotation of the scapula and pelvis, the length and proportions of their extremities, the length of the olecranon and calcaneum, the vertical direction and length of the metatarsal and metacarpal bones, the inclined direction and freedom of motion of the three phalanges of the fingers and toes, the number and relative distances of the joints,—all conspire to perfect the progression of these Ruminantia. They bound by the sudden flexion and extension of all the legs, which are lifted from the ground simultaneously, and which, after projecting the centre of gravity in a vertical direction, appear to arrive again synchronously on the plane of motion. They walk or trot upon the principle of other quadrupeds, as explained already in the Horse. The Deer and Antelope, celebrated for speed, bound over plains, ascend or descend mountains, and also possess the power of leaping across an abyss of great breadth, or down precipices twenty or thirty feet in depth without sustaining the slightest injury from the shock.

Proboscidia.—The enormous bulk of the head and body, and massive proportions of the osseous and muscular systems, are more largely developed in the ponderous Proboscidia than in any other known species of terrestrial quadrupeds. The dimensions of the bones of the extremities are proportional to the gravity of the superincumbent weight; the scapula and pelvis, as well as the axes of the scapulo-humeral and ilio-femoral cavities, are directed nearly perpendicular to the plane of progression, and the whole column in each extremity presents a less angular disposition of the axes of the bones than is found in the lighter and more agile solidungulous Pachydermata. The olecranon and calcaneum, as well as the trochanters, afford long and powerful levers for the application of muscular action. The ginglymoid

same species of animals may be considered nearly constant for all ages, sexes, and magnitudes.

* See Rennel on the rate of travelling of camels. Phil. Trans. 1791, p. 129.

articulations of the carpal and tarsal bones allow a very limited motion. The axes of these bones are inclined almost vertically, but those of the metatarsal and metacarpal bones are directed rather more horizontally. The phalanges of the toes diverge from each other to give a broader base of support to these great digitigrade quadrupeds: their walk is slow and heavy, and the order in which the legs move is the same as in the Solidungula.

Carnivora.—In the structure of carnivorous quadrupeds, such as the Lion and Tiger, we observe the strength of the more ponderous and slow-moving Ruminants, as the Ox, combined with the agility and speed of those lighter forms, as the Stag. This union of strength with speed is due to the geometrical and physical relations of the elements that enter into the composition of these powerful digitigrade Carnivora. The spine possesses greater mobility by the retraction of the spinous and transverse processes, and the trunk is of less weight and bulk compared to their muscular power than in the herbivorous ruminants. In the Lion the scapula, which is directed very obliquely forwards, is unfettered in its motions by a clavicle; the humerus is long and cylindrical, and has its axis directed downwards and backwards, forming, with that of the scapula, an angle of 110°; the radius and ulna are articulated so as to allow of pronation and supination; the olecranon projects several inches beyond the axis of rotation in the elbow-joint, and constitutes a powerful lever for the application of the tendons of the extensor muscles of the arm; the direction of the sacro-iliac articulation is eccentric to that of the sacrum, and the pelvis, which is inclined very obliquely backwards, forms, with the projection of the vertebral column, an angle of about 110°; the femur is directed forwards in standing at an angle with the pelvis of 84°; the tibia and fibula are distinct bones; the calcaneum is of great length; the tarsus and metatarsus inclined vertically, the phalanges horizontally; the last of which is elevated above the plane of motion.* In both the arms and legs the phalanges terminate in strong, curved, retractile claws for the prehension and laceration of prey. The posterior extremities in both the lion and tiger are longer, and the bones inclined more obliquely to each other than the anterior, giving them greater elasticity and power in springing: they walk, trot, and gallop upon the same principle as the horse.

Cheiroptera.—The bat being principally organized for flight, is provided with comparatively diminished powers of progression upon solids; the legs are feeble and incapable of supporting the trunk, and they move by a crawling, and sometimes a small leaping motion.

Quadrumana.—Of all Mammalia, the figure and organization of the Quadrumana approximates most nearly to man. They are destined to climb the trees of the forest; to leap from branch to branch; to walk, trot, or gallop as quadrupeds upon plain surfaces, with the trunk directed either horizontally, or to walk as bipeds upon the posterior extremities alone, with the trunk directed vertically. For these several positions of the trunk and modes of progression they are furnished with a suitable geometrical conformation of their osseous framework, more especially in the Ourangs and Chimpanzee. In the Quadrumana the spinal column has greater freedom of motion than in the Pachydermata and Ruminantia. The scapula, which is directed forwards at an acute angle with the vertebral column, is supported by a clavicle; the ginglymoid cavity is deep, for the secure rotation of the head of the humerus; the latter is long, but slender in the Hylobates or long-armed Gibbon; the radius and ulna are distinct and free from the motions of pronation and supination; the carpus is often composed of nine bones by the division of one in the second row, to give greater mobility to the hand; the metacarpus and phalanges are much lengthened, but the same in number as in man; the iliac bones, which are long and narrow, are directed backwards nearly parallel to the vertebral column, but presenting with it posteriorly a very small angle; the tuberosities of the ischium incline outwards, giving a large base of support to the animal when resting on its callosities. In the Hylobates, the femur is curved and of less length than the humerus, but it is nearly of equal length in the Chimpanzee and Ourangs. The tibia and fibula are long and slender; the articulations of the astragalus, calcis, scaphoid, cuboid, and cuneiform bones are directed obliquely, which gives to the ankle-joint a motion eccentric to the axis of the leg, the effect of which is to throw the animal upon the outer edge of the hands and feet. The long metatarsal and phalangeal bones are inclined upwards and inwards, by which they are adapted for prehension in climbing or standing on the branches of trees; the calcaneum is short, and its axis of motion is eccentric, with respect to the direction of the tendons of the gastrocnemius and soleus muscles; which, though not very powerful, act at a mechanical disadvantage tending to diminish their effective force in a twofold manner. In many Quadrumana, as the Cercopithecus and Semnopithecus, the lengthened and flexible tail is employed as an organ of prehension, but in the Macacus and others the tail is pendent, and not employed in their movements. In the Mandrills the tail is very short; the Simia, Pithecus and Simia Inuus have merely a tubercle, whilst the Ourangs and Gibbons are destitute of this organ altogether; the deficiency of the mass of extensor muscles of the ankle-joint in the Gibbons and Jockos is alleged by Daubenton * as a reason why these apes cannot maintain themselves in the erect position. Perrault is of opinion that the straightness of the ossa ilia prevents the extensor muscles

* It is in consequence of the direction which the tarsal, metatarsal, and phalangeal bones take, that the Carnivora and other animals are digitigrade.

* Encyclop. Méthodique Dictionnaire des Animaux, p. 20.

from acting with sufficient mechanical advantage to extend the thigh as perfectly as in man. Vicq D'Azyr * states, that in the Mandrills the flexors of the leg are inserted lower than the extensor muscles, and that they oppose the perfect extension of the leg upon the thigh, which renders it impossible for them to stand upright for any length of time without tottering. The Chimpanzee, the Ourang-Outang, and some of the Gibbons, however, are capable of walking upon their posterior extremities with the trunk nearly erect; but the pelvis being narrow, and the cotyloid cavities being directed inwards so as to throw the soles of the feet very near each other, the base of support becomes very much contracted, and the animal stands very unsteadily. Of all the Quadrumana, the trunk of the Chimpanzee is directed nearest the vertical; in walking as well as in conformation he approaches nearest to the figure and gait of man. In the Hylobates and Laniscus the arms are of sufficient length to enable them to touch the plane of motion with the fingers and assist them in walking; this is resorted to whenever the centre of gravity falls anterior to the base of support formed by the hind extremities.

The Lemurs are more decidedly quadrupeds; the large arc described by the spine, directed with its concavity downwards; the lengthened horizontal direction of the face to the direction of the scapular and cotyloid articulations, contribute to the prone position of the Lemurs. Some of the tribe, as the Lemur tardigradus, are denominated Sloths from their proverbially slow progression. Although the Ourangs have the advantage over other Quadrumana, of walking erect, and having the hands and arms free for prehension and great variety of action, such as using a club for defence or assault; yet the Gibbons outstrip the Ourangs in the velocity of their progression, and in their power of swinging and projecting themselves from tree to tree with extraordinary velocity. According to Duvaucel, the Hylobates agilis can launch itself from bough to bough at the distance of forty feet asunder, apparently without effort or fatigue. Martin relates, that "a live bird being set at liberty in the presence of a female Hylobates agilis, she marked its flight, made a long swing to a distant branch, caught the bird with one hand in her passage, and attained the branch with her other hand, her aim both at the bird and the branch being as successful as if one object only had gained her attention." The addition of a long and flexible tail in the Cercopithecus, Semnopithecus, and several other species, gives a fifth organ of prehension which is employed to assist them in a variety of motions. The walk, trot, and gallop of the Quadrumana are performed upon their four extremities on the same principles as those of quadrupeds in general, but as plantigrade bipeds their locomotion is accomplished like that of man.

Sect. V. *Man.*—The locomotion of man is that of a plantigrade biped. When the body is erect and the face inclined at a small angle above the horizontal plane, the head is exactly balanced on the atlas, and its weight is transferred to the latter with the least expenditure of muscular action: its axis of motion is bisected by a vertical line passing through its centre of gravity when it is in equilibrio upon the atlas: in every other position of the head the expenditure of muscular action is increased. It has been observed by Daubenton, that, when in the position of a quadruped, man is obliged to elevate the head above the axis of the vertebral column, in order to see directly forwards; and in depressing the head to the earth, the position of the occipito-atlantal articulation prevents the jaws reaching the ground. The movements of the head on the atlas are restricted to one plane, namely, the vertical; but its articulation with the dentata permits a horizontal motion through a large arc of a circle; the head cannot turn without the atlas, nor the atlas without the head; on the contrary, the atlas and dentata revolve upon each other in opposite directions. By means of these two joints, whose axes of motion are at right angles to each other, the head enjoys a considerable range both in the vertical and horizontal planes.

The vertebral column.—The office of this complex structure is purely mechanical. The flexibility of the spine is due to the twenty-four joints which divide its length, and the interposition of the elastic, intervertebral, fibrous tissues. It is upon the elasticity and quantity of the latter that the flexibility of the vertebral column depends. The mean proportions of the heights of the cervical, dorsal, and lumbar intervertebral elastic tissues to that of the bodies of the vertebræ are estimated by Weber as follows:

	MM.
Heights of cervical vertebræ	95.85
Dorsal "	242.95
Lumbar "	135.95

	M.M.
Heights of intervertebral tissues..	——
Cervical " ..	20.70
Dorsal " ..	34.90
Lumbar " ..	42.85

and their mean diameters,

MM.
15.
25.3
28.0

And, admitting their breadth to be equal to their thickness, which is near the truth, their tranverse sections will be as the squares of the breadths, or as 225, 640, 784. Hence, if the cervical, dorsal, and lumbar portions are curved with equal force, their angles of flexion due to their elasticity will be in the following proportions:

$$\left(\frac{20}{225}\right)^2 : \left(\frac{34.9}{640}\right)^2 : \left(\frac{42.8}{784}\right)^2 =$$

$$846 : 297 : 298$$

that is, the angle of flexion of the dorsal and lumbar portions, notwithstanding their unequal lengths, are nearly equal, whilst the angle of the cervical portion, though of much less

* System Anat. des Animaux.

length, will be nearly three times greater. The greatest flexion of the trunk is in the plane of its mesial section, and results chiefly from the cervical and lumbar vertebræ. According to Weber, its greatest twisting or torsion horizontally is derived from the dorsal region. The angles of flexion of the head and trunk in two cases were as follows:

	Crown of the head and sternum.	Sternum and sacrum.	Sum of the two.
1	147°	83°	230°
2	175°	85°	260°
Mean..	161°	84°	245°

Of these two cases nearly two-thirds of 245° are accomplished by the head and neck, and one-third only by the dorsal and lumbar vertebræ.

The curved form of the spine, somewhat resembling an italic *f*, instead of being a cause of weakness, is, on the contrary, a source of strength and security; for forces acting vertically upon it are transmitted obliquely, thus diminishing their mechanical effect; and the elasticity of the intervertebral tissue prevents the shock to which the bones would otherwise be subjected at every step in walking. With respect to the power of the vertebral column to sustain weight, if we regard it in consequence of its form and elastic intervertebral substance as a spring with small flexures, it is capable of bearing a greater weight than if it were straight, in the proportion of the square of the number of curves plus one to unity; that is, a weight sixteen times as great. Considered as a whole, the vertebral column represents a lever of the third order, of which the fulcrum is in the axis of the articulation of the fifth lumbar vertebra with the sacrum: the *power* is the mass of muscles inserted into the sides of the vertebræ; and the *resistance*, the weight of the head, soft parts of the neck, the thorax, and part of the abdomen.*

In standing erect, the direction of the vertebral column is perpendicular to the horizon. Weber found, by means of plumb-lines let fall on each side opposite the centre of the heads of the femurs on which the trunk is balanced in the erect position, that the transverse vertical plane intersected both ends of the spine, passing through the atlanto-occipital articulation above and the sacro-lumbar below; he found also lying in the same plane the two mastoid processes and the centres of the ankle and knee joints.

Viewed separately, each vertebra represents a lever of the *first* order, whose fulcrum is the next vertebra, on which it rests; the *power* and *resistance* are the muscles acting upon it in different points alternately. The spinal column of animals is a flexible lever, destined to move and support a multitude of organs, and to connect the more distant parts of the skeleton with each other. We have nothing in the structure of locomotive or other machines bearing the least resemblance to its mechanism; and if, with Sir C. Bell, we compare it to the mast of a ship, it will tend only (as Dr. Arnott has already pointed out) to convey an erroneous impression, both of its structure and its functions.

In standing, the vertebral column transmits the weight of the organs appended to or supported by it by means of the sacrum to the pelvis. The pelvis is a lever of the *first* order, having its *fulcrum* in the ilio-femoral articulations on the heads of the femurs; the *power* and *resistance* are the muscles acting anteriorly and posteriorly to the axis of rotation.

In the erect position of the trunk the pelvis is inclined to the direction of the vertebral column. The angles, both of the superior and inferior margins, have been measured by Naegele and Weber. According to the former, the mean angle of inclination of the superior margin to the horizon is 60°, and to the vertebral column 150°. The inclination of the inferior margin with the horizon 11°, and with the vertebral column 101°. The angle which the pelvis forms with the vertebral column permits the femurs to extend farther backwards, and to increase their range of oscillation. The magnitude of the transverse diameter of the ring of the pelvis determines the distance of the heads of the femurs from each other, and throws the thighs sufficiently apart, to prevent their friction upon each other in walking. The pelvis can rotate only on an axis perpendicular to the plane of the mesial section, when the body rests equally on both legs, but can turn horizontally upon the heads of either femur whilst the body rests on one leg. In standing, the pelvis is kept in equilibrio by several forces. The weight of the abdominal viscera, lying anterior to its axis of rotation upon the femur, tends to depress the pubes, and rotate the pelvis forward, while the weight of the vertebral column, acting posterior to that axis, tends to swing it backwards.

The weight of the vertebral column preponderates over the parts lying anterior to the axis on which the pelvis rotates, and consequently would require a considerable expenditure of muscular action to keep it in equilibrio on the femurs, but the obliquity of the vertical axis of the pelvis to that of the vertebral column throws the resultant of all the forces, acting downwards upon it, near the axis of rotation, which tends to preserve the balance; added to which, the muscles which draw the vertebral column backwards, having one of their points of insertion in the sacro-iliac section of the pelvis, tend to elevate it, and to neutralize their action on the vertebræ in an opposite direction. The principal agents in keeping the pelvis in equilibrio are the powerful muscles acting between it and the thigh.

The pelvis receives the whole weight of the trunk and superposed organs, and transmits it to the heads of the femurs. It has two axes of motion, one of which is on the last vertebra, and the other in the ilio-femoral articulation; in both cases it acts as a lever of the *first* order.

The legs.—The leg moves by means of three joints, namely, the ilio-femoral, the knee, and the ankle. In the erect posture the first of these allows the leg to move only forwards, the

* Vide Majendie Phys., by Dr. Milligan, p. 175.

second only backwards, and the third neither backwards nor forwards.

The length of the legs, measured from the hip-joint to the ground when standing erect, preponderates slightly over that of the body when taken from the distance of the crown of the head to the axis of the hip-joint, consequently the centre of gravity is raised above the plane of position rather higher than the semi-distance from the head to the ground when the entire sole of the foot is in contact with the earth.* In consequence of the lengths of the femur and tibia being nearly equal, and of the zigzag direction which the limbs take during flexion, and because the angle of the greatest flexion of the knee-joint is nearly equal to the sum of the angles of the hip and ankle, it results that in the simultaneous flexion of these three joints, (provided the angle of inclination of the foot to the ground continues 30°,) the trunk preserves its erect position as when standing, and therefore ascends and descends (by the flexion and extension of the legs) in the same vertical line. The greatest amount of elongation and contraction of the leg resulting from the greatest extension and flexion of the hip, knee, and ankle-joints, may be easily ascertained by measuring with a line from the hip-joint to the head of the astragalus during such flexion and extension, and marking the difference in the length of the line in the two states. By this method the length is estimated by Weber as follows:

	m.m.
In the greatest state of extension..	924.26
In the greatest state of flexion....	404.74

The actual lengths of the several portions of the leg are

	m.m.
Head of the femur to the condyles..	380.0
From the condyles to the convex articular surface of astragalus ..	420.0
Axis of articulation of the astragalus to centre of foot	136.0

During the greatest extension the first three of these points of the leg formed an angle of 148°8′, and during the greatest flexion an angle of 40°. The second, third, and fourth points form in the greatest extension an angle of 157° 4, and in greatest flexion 94° 6′.

The proportion between the greatest and smallest length which the leg can assume varies but little.

Figs. 247 and 248 from Weber show the greatest amount of extension and flexion which the leg can effect; the corresponding difference in length is as 14 to 5, but in walking and running the flexion is less, and the difference of length as 11 to 9.

In standing, the weight of the body is transmitted from the pelvis to the heads of the femurs; the oblique directions of the latter upwards and inwards keep in equilibrio the vertical forces downwards and outwards produced by the weight of the body on the wedge-like sacrum.

The femurs transmit the weight impressed

Fig. 247.

Fig. 248.

on them by the trunk, together with their own weight and that of the soft parts to the tibiæ. The shafts of the latter are straight, and by their prismatic form their solid contents are removed further from the axis of the bone, which enables them to support a greater weight with less expenditure of materials.

The fibula adds likewise to the strength of the tibia, both vertically and laterally; the latter transmits, in its turn, its own weight and that of its soft parts to the astragalus.

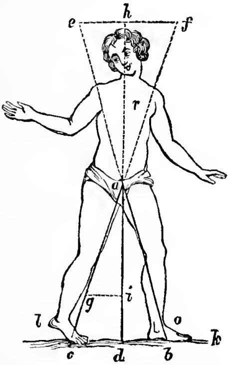
The astragalus transmits the pressure made upon it partly to the calcaneum and partly to the scaphoides; the calcaneum partly to the ground and partly to the cuboides; the scaphoides transfers the force through the cuneiform bones; the toes to the ground, where the base of support terminates, supposing the entire foot to rest on it. In the mechanism of the foot we discover an elastic arch, upon which the shock of the body is received, and transmitted obliquely to the ground. This admirable structure prevents the jar which the body would otherwise sustain at each step by the re-action of the ground in walking, running, leaping, or falling; but an exact investigation of the mechanism of the foot would occupy more space than we have assigned to this subject. The areas of the soles of the two feet and the space lying between them is the whole base of support in standing on both legs; but when standing upon one only, this is diminished, not only by the area of one foot, but also of the space lying between them. In the latter case, the base is so narrow that the act is not easily accomplished, but the difficulty of keeping the trunk in equilibrium is vastly increased when the base of support is reduced to the area of the great toe, as is accomplished by opera dancers; or to the area of one-fifth or two-fifths of a square inch as in skating, or to one still less, as in rope dancing, wherein the base of support oscillates laterally. In this latter case, the difficulty is increased by the necessity of keeping the trunk in equilibrio, but the centre of gravity is retained in the plane of the rope by fixing the eye on some distant point in it. The position which the two feet ought to take, when equally advanced and equally inclined, so that

* See positions of the centre of gravity, sect. i. p. 409.

they may form the greatest base of support, has been mathematically investigated by Parent and Barthez. According to the latter, the trapezium which forms the base of support will be a maximum when the prolongations of the lines drawn through the central line of each foot and passing through the centre of each heel form an angle of 38° 56″.

The calculation of Parent is defective, from its being based upon the hypothesis that the foot turns as upon a pivot about its articulation with the leg, instead of around the heel. When the body stands erect upon both legs, and presses equally on each, the legs will form equal angles with the vertical line passing through the centre of gravity; but if the two legs form different angles with that line, the pressure upon the legs will be unequal, and will vary with the angles of inclination, for example, in *fig.* 249, *a d* is perpendicular and *g i* parallel to the horizon; if *a b*

Fig. 249.



and *a g* represent the entire force exerted by the legs to support the whole body, *a d* and *a i* will be the corresponding portion of these forces necessary to sustain the weight of the body, and will also together represent that weight; and if *a d* and *a i* be found by experiment, the absolute forces, *a b*, *a g*, will be found.* In standing, the limbs serve merely to support the body, and to preserve the centre of gravity at a certain height above the plane of position, within the base of support, which is a necessary condition to prevent it from falling. In addition to these functions they translate the trunk, during progression, from point to point, and keep it in equilibrium, in all the varied movements and under the action of all the extraneous forces incidental to locomotion.†

* See Borelli de motu animal. prop. 138, p. 173.

† When a man stands with his centre of gravity at a vertical height H, above the plane of the horizon, if his weight be P, then the amount of force which he expends in order to stand is, according to Poisson, equal to PH.—Traité de Mech. Paris, 1833, § 688.

Walking.—In walking or running, the body may be divided into two portions, namely, the trunk, head, neck, and arms, which constitute the burden that is to be borne, and the legs which support and carry the burden along. The former cannot, however, be considered as a merely passive or dead weight, as the trunk and arms contribute to keep in equilibrio the forces acting on the centre of gravity during progression. In walking, the trunk is carried forwards with its major axis directed nearly perpendicularly to the horizon, like a rod poised endways on the hand. The power to keep the trunk thus poised whilst it is moved forwards is attained only after considerable experience during the earlier period of man's career, when his unsteady gait, numerous trials, and frequent falls afford practical illustrations of the difficulty of the process. Every movement of the legs, arms, head, or trunk, as well as the bearing of burdens in various positions, requires a compensating movement of some other part, in conformity to the theory of parallel forces, to preserve the whole in equilibrio; therefore, in order to keep the supported parts poised on the rounded head of either femur, whilst the body is transferred from one to the other, and carried forwards in the air, either against or in the same direction as the wind, there must be a continued interchange of compensating movements, and these actions are placed under the controul of the excito-motory division of the nervous system. It is well known that when any portion of a rigid body receives motion from a neighbouring body, all the parts of the rigid body will partake of the same motion, only when the direction of the force passes from the point of contact through the centre of gravity. If this is not the case, as, for example, when the upper extremity of the propelling leg acts on the lower part of the trunk of the human body in the erect position, the lower part would be propelled forwards and upwards, whilst the centre of gravity of the trunk would be left behind, and fall backwards; but if this centre be inclined forwards at the beginning of the step, the weight of the body and its required momentum will propel it forwards and downwards; hence the resultant of the several forces will be a force which propels the body forwards in a direction which, by experience, is found to be nearly horizontal: but there is also another force which affects the trunk, namely, the resistance of the air, which tends to turn the trunk backwards, and must be counteracted by the force of gravity, through the inclination of the trunk forwards. The amount of this constant inclination of the trunk must be estimated by the resistance which it encounters from the air in walking and running. It must therefore be greater in rapid progression, because the resistance of the air is then more powerful than in more deliberate motion. Without this inclination it would still be possible to preserve a uniform position of the body in walking and running, not, however, by the force of its own gravity, but by means of the power of the muscles, which connect it with the limbs; but this would require a great expenditure of muscular force, which is avoided by the inclination of the trunk. That this inclination really takes place is confirmed by experience, and its amount has been measured by Weber, both in walking and running with various degrees of velocity. In order to take these measures with accuracy, a given path was passed over, sometimes in running and sometimes in walking, with various degrees of speed, the time being measured and the steps counted. By means of a telescope, placed sideways to this path, the difference of inclination in walking and running was ascertained, but as it was extremely difficult to find the actual position of the centre of gravity of the trunk in such varying positions, a conspicuous line marked on the trunk was substituted for the vertical line passing from the axis of the femurs through the centre of gravity, and thus its slightest deviations were observed. The vertical position of the trunk when at rest may be exactly estimated by the angle which it makes with this marked line in walking to and fro, in running to and fro, and in standing in the two opposite positions. The last angle, deducted from each of the two first, gives the double inclination of the trunk from the vertical in walking and running. The results of these measurements are given in the following Tables.

TABLE 1.

Measure of the inclination of the trunk in walking and running.

1.509	0.320			

We therefore conclude that when we vary our steps, the velocity of the upper ends of the legs, together with a corresponding inclination, is communicated to the trunk. The trunk, then, as has been before observed, exactly resembles a rod balanced on the finger and carried forward; the inclination in both cases depending on the laws of mechanics.

The force of the muscles which keep the trunk in a state of equilibrium is likewise economized in walking and running by the regular oscillations of the arms. The distance of the scapulo-humeral articulation from the axis on which the trunk freely moves, gives any force applied at the shoulder-joint a considerable mechanical effect on the trunk. In progression the arms and legs move simultaneously in the following order. Whilst the right leg swings forwards, the trunk is turned round horizontally on the head of the left femur, and would propel the right shoulder before the left, but at the same time the right arm swings backward and the left forwards, and by generating a force in an opposite direction neutralises this tendency. A corresponding compensation takes place when the left leg swings forward, and this is effected by a good walker, without any sensible lateral twisting of the trunk. The length of the arms is so adjusted to that of the legs, that they oscillate with the latter in small curves simultaneously. Weber has computed the duration of a single oscillation of the arm, hanging straight down, at 0″.63, and when bent at right angles at 0″.53. The pace is less constrained and less fatiguing when the arms are allowed to accompany the movements of the legs without muscular effort. When the body is put in motion, the momentum generated requires an equal force in the opposite direction to stop it, for which purpose the trunk is thrown back; and this, with the resistance of the feet on the ground, will commonly suffice. When, however, this is not the case, the motion must be arrested gradually, or, as it often happens when the plane of position is composed of ice, the leg goes on without the trunk, and the centre of gravity comes to the ground.

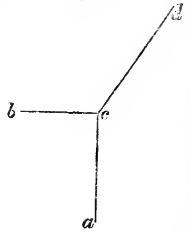
In walking, the trunk is also elevated and depressed at each step vertically, as well as oscillated in other directions. By the assistance of a rod graduated into millimetres, which was carried at the head of the trochanter major by the ambulator, and viewed through a telescope, Weber was enabled to ascertain the amount of the elevation and depression of the trunk. He found that when the length of the steps treading on the whole sole of the foot measured 2.39 feet, the mean elevation and depression were 1.1 inches. The plane in which the rod vibrated, and the magnitude of the oscillations, did not appear to vary materially, whether the speed was accelerated or retarded. In walking on the ball of the great toe the mean elevation and depression of the trunk was 0.8 inch.

Estimate of the forces employed in walking. The forces which we have to estimate in walking are, first, that of the extension of the leg; secondly, the gravity of the body; thirdly, the resistance which the body encounters in progression. Of these, the first is that force which the leg exerts by its extension to bring it into a straight line, as if both of its extremities (viz. the head of the femur, and that part of the foot which is in contact with the ground) endeavoured to push each other away. The direction of this force depends on the position of the extremities of the leg; but whatever that direction may be, it is always resolvable, on the principle of the parallelogram of forces, into a vertical and a horizontal component. The vertical portion of the extension upwards is equal to the *second* force, or the gravity of the body acting vertically downwards; in this case the centre of gravity remains at the same height above the plane of progression. The horizontal portion of the extension produces an increased velocity in the horizontal direction, the magnitude of which depends on the position of the supporting leg. By means of these forces the body is propelled forwards. At the moment the body receives the impulse of extension it is accelerated until the *third* force, namely, the resistance,* augmenting continually with the velocity, is equal to that of the acceleration; when these two forces neutralize each other, the body will move forwards with an uniform velocity.

Hitherto the forces which influence walking have been considered as if they were uniformly accelerating forces; but though they are not strictly such, yet as they recur at the end of each step, the mean velocity of the body will remain the same as if they actually were so.*

Let us assume a common point of application of the forces, and consider this as the centre of the body, or the point of separation between the trunk and the legs. The three forces may be represented (*fig.* 250) by three straight lines meet-

Fig. 250.



ing at this point, thus: Let c be the centre of the body; draw $c\,a$ in a vertical direction, $c\,b$ in a horizontal, and $c\,d$ in the direction of the prolongation of the leg on which the body is supported. These three lines will represent in magnitude and direction the forces which are in action during progression, if they be so taken that either of them equals the diagonal of the parallelogram formed by the other two, and will coincide in direction with that diagonal produced beyond c. Messrs. Weber do not consider those physiologists worth refuting who state that the forces which propel the body forwards exceed those that drive it back, for in that case, from the continued preponderance of force in one direction, there would result, not an uniform, but a continually increasing velocity. An uniform motion in a straight line can only take place either when no force whatever is exerted on the moving body, or when all the forces by which it is affected are in equilibrium.

In order to investigate with greater precision the laws which regulate the movement s of the body, the Messrs. Weber have considered the weight of the trunk to be collected at the point of junction of the legs, and the weight of each leg, supposed a straight line, to be collected in a point at a given distance from that junction. The movements of these points are supposed to take place in the same vertical plane. They have then applied the general equation for the motion of a system of material points,† and deduced by means of it that the raised leg, in walking, swings forward like a pendulum, the length of which is the above-mentioned given distance, but in consequence of the motion of the point of junction, which is supposed to

* The principal resistance is occasioned by the advanced leg when it reaches the ground. Other resistances are the frictions of the joints, of the sole of the foot upon the earth, of the air, &c., but these are very trifling when compared with the retardation caused by the advanced leg.

* The three forces which influence walking are so related to each other, that each of them is equivalent and opposite to the resultant of the other two.

† See Poisson's Traité de Mechanique, Paris, 1833, vol. ii. § 531.

move uniformly in a horizontal line, it has a retrograde motion in its curve of oscillation, which, if measured from its lower extremity, is just equal to the velocity of the point of junction, when estimated in the direction of the tangent of the curve at the commencement of the step. Hence, in quick walking, when the swinging leg is supposed to come to the ground in a vertical position, it describes half of the curve during each step. By following the same course of reasoning Messrs. Weber have ascertained the amount of the vis viva, or vital force, communicated to the swinging leg in any given time; the amount communicated to the body by the standing leg; the proportion which the time when the body is supported on one leg bears to the whole time of a step; and the height at which the centre of gravity is borne above the ground.* In order to verify the pendulous movements of the legs a person was placed upon a small block, and by supporting himself on one leg, suffered the other, measuring thirty inches, to swing, with relaxed muscles, as a pendulum. A vibratory motion having been communicated by a slight movement of the trunk backwards and forwards, the number of oscillations made in the time of a minute were found to be 84, consequently

$$\frac{60''}{84} = 0''.714285 = \text{time of one oscillation};$$

and since the lengths of pendulums at the same place vary inversely as the squares of the numbers of oscillations in a given time, $84^2 : 60^2 :: 39\frac{1}{8} : l$ (the length of a pendulum which vibrates synchronously with the leg); hence $l = \frac{60^2 \times 39\frac{1}{8}}{84^2} = \frac{140850}{84^2} = 19.961$ inches. Now as the whole length of the leg was 34 inches, the centre of oscillation must be less than two-thirds of that length from the point of suspension, and consequently less than in a prismatic rod, the length of which is such as will vibrate synchronously with the leg. This accords with the known figure of the leg, the mass of which diminishes as the distance from the axis of motion increases. The time of a half oscillation of the freely suspended leg which we have found $\frac{0''.714285}{2} = 0''.3571425$, approximates very closely to that found by the Webers, both in the living and the dead subject.

The second experiment was made by our engraver, Mr. Vasey. In walking at the rate of four miles per hour he counted 2000 steps every fifteen minutes; then $\frac{15 \times 60}{2000} = 0''.45$ the time of each step; now as 2000 steps were taken in one mile of 5280 feet, the length of each

* After an elaborate analysis the Messrs. Weber have deduced the following equations, which express the general laws of walking.

$$h^2 + p^2 = l'^2 \quad \ldots\ldots (23)$$

$$(h - \tfrac{1}{2} g\,\theta^2)^2 + p^2 = l'^2 \quad \ldots\ldots (24)$$

$$\frac{t}{\tau} = 1 + n \operatorname{Cos} \left\{ \frac{\pi}{T} (t - \alpha) \right\} \quad \ldots\ldots (25)$$

$$h = k\,(\tau - \theta)^2 \quad \ldots\ldots (26)$$

$$\theta = \frac{3 - \sqrt{1 + \frac{g}{4k}}}{2 - \frac{g}{k}} \frac{\tau}{2} \quad \ldots\ldots (27)$$

$$r = \frac{g}{l} \frac{T^2}{\pi^2} \quad \ldots\ldots (28)$$

In which equations

$$n = \sqrt{1 + \frac{r h^2}{l g \tau^2}}.$$

$$\alpha = \frac{T}{\pi} \operatorname{arc} (\operatorname{Cos} = \frac{1}{n}).$$

$$k = \frac{(\mu + 1) g}{\left(1 + r n \tau \frac{\pi}{T} \operatorname{Sin} \left\{ \frac{\pi}{T} (t - \alpha) \right\}\right)^2 - (1 - r)^2}.$$

The mass of the trunk is supposed to be concentrated in a point m at the upper end of the leg, and the mass of the swinging leg in a point m' in the leg which is considered as a straight line.

l is the length of the hinder leg at the beginning of a step.

h is the height of m above the horizontal plane at that time.

p is the distance between the hinder foot and the forward at that time, or the length of a step.

θ is the time during which m falls below its horizontal line at the end of the time t.

l' is the length of the hinder leg at the end of the time θ before it is extended or becomes l.

τ is the time of one step.

t is that portion of it during which the leg is swinging.

r is the ratio of the distance between m and m' to l.

g is the accelerating force of gravity = 32.5 feet.

π is the number 3.1416.

T is the time of an oscillation of a pendulum whose length is rl.

μ is the ratio of the mass of the trunk to the mass of the swinging leg.

The quantities l' T, μ must be previously ascertained, and π and g being always the same, there will be nine equations for finding the values of the ten remaining quantities; if therefore we know any one of these ten, the rest may be found.

In regular progression the force communicated by the supporting leg to the trunk must equal that imparted by the trunk to the swinging leg, that is

$$m'\left(c + r n p \frac{\pi}{T} \sin \left\{ \frac{\pi}{T} (t - \alpha) \right\}\right)^2 - m'(1 - r)^2 c^2 = \frac{m + m'}{h} g\,p^2 \frac{2t - \tau}{\tau},$$

from which, by substituting $\frac{p}{\tau}$ for c and μ for $\frac{m}{m'}$ we get equation (26.)

Fig. 251.

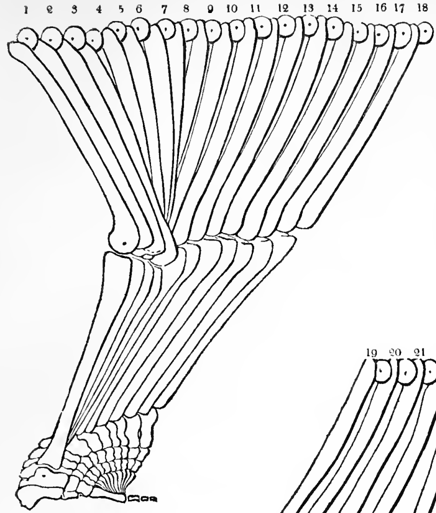


Fig. 251 *shows the consecutive positions of the leg during two successsive steps. To render them more distinct they are divided into two groups. The* 18 *figures of the first group show all the positions through which the leg passes while the toe rests upon the ground. The* 10 *of the second show the successive positions during the time the body is carried forward by the swinging leg. The positions from* 1 *to* 4 *show that division of time of the first step, when both legs are on the ground; the figures* 5 *to* 14 *give the portion of time of the first step when one leg rests on the ground while the other swings; from* 15 *to* 18, *that division of the second step where both legs rest on the ground; No.* 19 *to* 28 *show the portion of time when one leg swings while the other rests on the ground.*

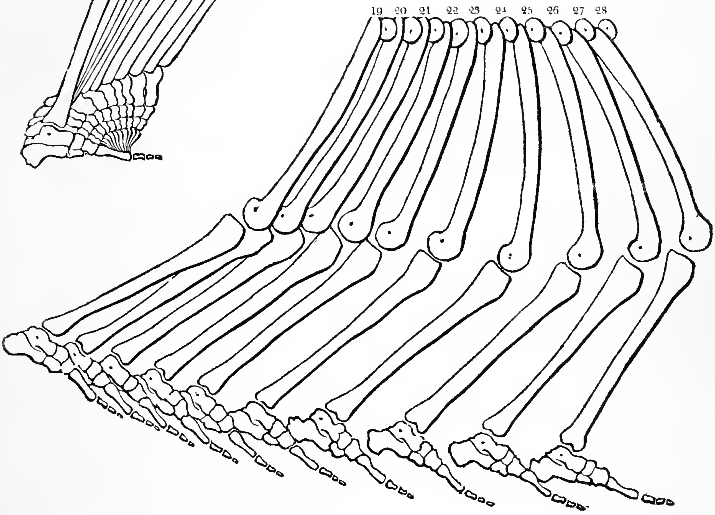

step must have been $\frac{5280}{2000} = 2.64$ feet. In this case also the length of the leg was 34 inches, which gives 19.961 inches for the length of the synchronous pendulum, and for the time of each half oscillation $0''.357$; hence the time of taking each step was longer than the time in which the leg was susceptible of swinging without muscular effort, as a pendulum, by about $0''.093$.

The step is considered as commencing at the instant when the hindmost leg is raised from the ground. Let us then suppose the whole sole of the foot of the right leg, which is in advance of the left, to be in contact with the ground, upon which it acts as a fulcrum; the hip, knee, and ankle-joints to be in a state of partial flexion, and the line from the head of the femur to the ankle-joint to be vertical, as in *fig.* 251, No. 4. In this position, the right leg supports the whole weight of the trunk, and the left, being extended obliquely backwards, does not contribute to the support of the burthen. The flexed position of the right leg lowers the centre of gravity, and the effective portion of the force of extension, acting only in a vertical direction, produces no horizontal motion. At this moment, the left leg having previously communicated a slight horizontal impulse to the centre of gravity, and the trunk being inclined forwards, the head of the femur of the right leg is propelled from No. 4 towards No. 18. The leg, instead of being vertical, is now directed obliquely forwards and upwards. In order that the head of the femur with its load may be sustained at the same height above the

Fig. 252.

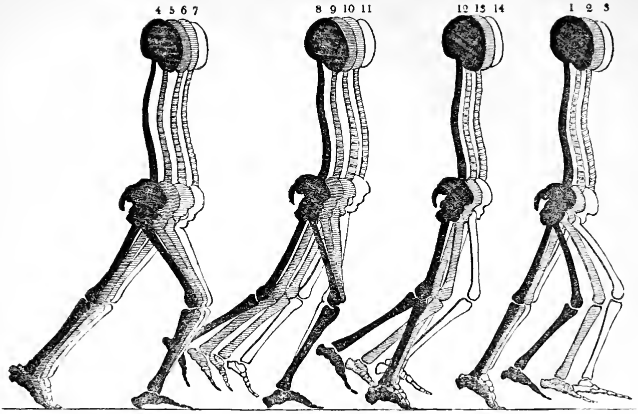

Fig. 252 *shows the simultaneous positions of both legs during a step, divided into four groups. The first group,* 4 *to* 7, *gives the different positions which the legs simultaneously assume while both are on the ground; the second group,* 8 *to* 11, *shows the various positions of both legs at the time when the posterior leg is elevated from the ground, but behind the supported one; the third group, No.* 12 *to* 14, *shows the positions which the legs assume when the swinging leg overtakes the standing one; and the fourth group,* 1 *to* 3, *the positions during the time when the swinging leg is propelled in advance of the resting one.*

plane of motion, whilst it moves forwards with the trunk, from No. 4 to 18, the distance from the head of the femur to the foot must be constantly increasing. To accomplish this the muscles which extend the hip, knee, and ankle-joints are gradually contracted, and the length of the leg sufficiently increased by its extension to reach from No. 18 to the ball of the foot (*fig*. 251). In these movements the sole of the foot rotates on the ground, and (independently of the angle formed by the legs) increases the length of the step by the length of the foot from the heel to the ball; because, when the head of the femur arrives at No. 18, *fig*. 251, the line from the ankle-joint to the ball is perpendicular to the ground. At the moment that the head of the femur of the left leg arrives at a position vertical to the foot, as No. 4, *fig*. 251, the right leg is lifted from the ground,* and, from its oblique position and weight, swings forward like a pendulum, whose axis of motion is in the hip-joint, Nos. 19 to 28, *fig*.251, and having passed by the supporting leg it touches the ground, with the ankle-joint in advance of the head of the femur, No. 1, *fig*. 251. The heel is first placed upon the earth, and by degrees every part of the sole, the hollow arch only excepted, is brought into contact with the ground, and the head of the femur is again over the ankle-joint, as before, No. 4, *fig*. 251. The motion of the left leg alternates with that of the right in the same manner.* In the first period of the movement the left leg is seen in the rear of the right leg, No. 8 to 11, *fig*. 252. Having overtaken the latter, No. 12 to 14, *fig*. 252, it advances before it and comes to the ground in sufficient time to receive the weight of the body as soon as the right leg ceases to act, No. 4, *fig*. 252, so that the instant the weight of the trunk is transferred to it from the right leg bending slightly and returning to its former position, it acts like a spring, and prevents any sudden concussion arising in consequence of the translation of the burthen from one leg to the other. The weight of the trunk being thus propelled, supported, and transferred from one leg to the other alternately, a constant and uniform movement in a horizontal direction is maintained. The right and left leg having thus swung and supported the body alternately, and having been on the ground simultaneously a short, and separately a long, period, the horizontal path of the centre of gravity, during these two movements, is equal to the length of a double step. In consequence of this interchange of offices the supporting leg is active, whilst the swinging leg is comparatively pas-

* Measure of the elevation of the heel and toes in walking, the distance passed through 30 metres.

* The Webers compare the action of the foot to the rolling of a wheel, with this difference, that the rotation of the wheel is uninterrupted, whilst that of the foot is terminated and renewed at every step. In walking on the ball of the foot, or on the toes, the rotation is confined to the distance between the ball of the foot and the point of the toes.

sive; that is, it swings forwards by the force of gravity alone, independently of muscular action. The supporting leg is regarded by the Messrs. Weber as a substitute for the propelling weight of a clock, and the swinging leg as the substitute for the pendulum, both exchanging their offices alternately. The distance from the point where the ball of the foot of the swinging leg quits to the point where it is again placed on the earth, is equal to the length of a double step. This outline of the action of the legs in walking depends on principles which we shall now proceed to investigate more strictly, in doing which we shall draw largely from the theoretical and experimental researches of the Messrs. Weber, whose labours have contributed so extensively to advance our knowledge in this interesting branch of human physiology.

The positions of the body in walking at various instants of time have been described both by Borelli and Weber; it is thus represented by the latter. Let *fig.* 253 be the vertical, and *fig.* 254 the ground plan, on planes in a straight

Fig. 253.

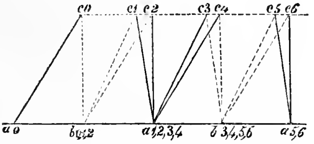

Fig. 254.

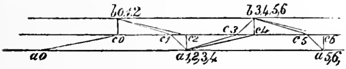

horizontal path. In *fig.* 253 the simultaneous positions of the two feet are represented at the moment when they reach the ground, also the position of the centre of gravity of the body in the vertical plane. The position of the right leg is shown by the continued lines, and that of the left leg by the dotted lines. The extremity of the right foot is designated by the letter a, that of the left by the letter b, and the centre of gravity by c, the contemporaneous positions of these points being denoted by the numerals annexed to these letters. In the horizontal projection, *fig.* 254 represents the simultaneous position of both legs and of the centre of gravity: the letters and figures are the same as in the preceding diagram. At the instant when the hinder leg is raised from the ground at the commencement of each step, the extremity of the forward leg and the centre of gravity lie in the normal plane of the line of progression; for example, at the beginning of the first step, b_0 and c_0, of the second step a_2 and c_2, and of the third step, b_4 and c_4, lie in the normal plane of the direction of progression.

In each step the extremity of one leg must be advanced as far before the foot of the other as in the preceding or following steps the other leg was placed before the first, for example:— in the first step, the foot, $a_{1\,2\,3\,4}$ must advance so far before $b_{0\,1\,2}$, as in the second step $b_{3\,4\,5\,6}$ must advance before $a_{1\,2\,3\,4}$.

The time of each step, that is, the space of time between the raising of each foot in succession, is subdivided by Borelli and the Webers into two parts, namely, one part in which one leg, and the other when both legs are on the ground: for instance, during the first step, while the centre of gravity advances from c_0 to c_1, one leg, and, while it advances from c_1 to c_2 both are on the ground. In the second step, while the centre moves from c_2 to c_3, one leg only, but while it advances from c_3 to c_4 both legs are again on the ground, and so on in succession. But there is no instant in walking in which the body moves freely through the air without either leg touching the ground, as in running.

The sum of the squares of the elevation of the centre of the body above the horizontal plane, and the length of the step, is equal to the square of the length of the extended leg.* This proposition depends on the circumstance that the forward leg stands vertical to the ground at the instant the hinder leg quits it; and that the two legs, with the horizontal distance between them, form, at this moment, a right-angled triangle. According to the Webers, the body, in walking, continues to be affected by the extensor power of one leg only, because the expenditure of the extensor power of the legs to support the body is only just sufficient to sustain it; and this expenditure is at a minimum only when the *forward leg* bears the whole burden during that period in which they are both on the ground, for as the forward leg acts at a less angle than the hinder leg, it is capable of supporting the body at a much greater mechanical advantage, which is at a maximum when it stands vertically. MM. Weber also find that the body is accelerated whilst one leg, and is retarded whilst both legs are on the ground; for, in slow walking, the forward leg being placed on the ground in advance of the centre of gravity, it tends for an instant to check the horizontal velocity of the body.

We shall now take a brief view of the velocity in walking, and of the principles on which it depends. MM. Weber have shewn that the velocity in walking varies with the height at which the head of the femur is carried from the ground; as this height *increases*, the velocity *decreases*.† The length of each step decreases as the height of the centre of gravity increases; for the greater the elevation, the less will be the distance to which the leg will extend; therefore corpulent persons, and porters with heavy burdens on the shoulders, take steps of diminished length. The duration of a step,

* Hence we get eq. 23.

† The velocity being uniform $= \frac{p}{\tau}$ and therefore increases as h decreases.

also, depends on this height. When the centre of gravity is most depressed, the swinging leg must be placed on the ground in the vertical position, instead of being suffered to pass beyond it, as it does in slow walking. In quick walking the propelling leg acts more obliquely on the trunk, which is more inclined, and forced forwards more rapidly than in slow walking. The time when both legs are on the ground diminishes as the velocity increases, and it vanishes altogether when the velocity is at a maximum.

TABLE 5.

Measure of the velocity in quickest walking. Space traversed 47 metres.

Number of Steps.	Time.
53	17.57
54	18.00
55	18.20
54.5	18.18
55	18.42

54	17.92
55	18.10
54	17.77
54	18.05
54.3	18.021

From this table we observe that the velocity in quickest walking is at the rate of 2.608 metres, or about 7.897 feet per second. In conducting their experiments the MM. Weber found that the velocity was constant, whether the power of the muscular system had been renovated by repose, or exhausted by fatigue, and therefore they concluded "that so long as the muscles exert the general force necessary to execute locomotion, the velocity depends on the size of the legs and on external forces, but not on the strength of the muscles."

0.742	0.659	0.89	0.817

TABLE 10.

In the following table we find the proportion between the duration of the step and the time of the leg resting and swinging during very diversified paces.

Duration of Step.	Duration of Standing.	Duration of Swinging.
″0.344	″0.341	″0.347
0.376	0.400	0.352
0.429	0.484	0 374
0.523	0.570	0.476
0 742	0.817	0.667

These experiments prove that the time in which the leg is swinging is least in the quickest pace, and is equal to half the whole time of oscillation of the leg; that it increases in proportion as the step becomes slower; that, consequently, that division of time which the swinging leg occupies in describing its entire curve is increased by one-half of the entire portion of time, and more in proportion as the pace becomes slower. This gives rise to another range of experiments which have been made by the Messrs. Weber with the same design, of which the following table is the result.*

TABLE 11.

Experiments on the time in which the leg stands on the ground, with various degrees of velocity in walking.

Duration of Step.	Length of Step.	Velocity.	Duration of the Leg resting.
″	m.		″
0.317	0.820	2.587	0.317

0.317	0.317	0.317
0.430	0.513	0.347
0.463	0.504	0.422
0.582	0.694	0·472
0.660	0.782	0.538

The *number* of steps which a person can take in a given time in walking depends, first, on the length of the leg, which, governed by the laws of the pendulum, swings from behind forwards: secondly, on the earlier or later interruption which the leg experiences in its arc of oscillation by being placed on the ground. When the hinder leg has quitted the ground, it swings forward by its own gravity, in consequence of its freedom of motion in the ilio-femoral articulation and its oblique position; and, in order that the body may be supported, it must, at least, move so far forwards that the foot may arrive at a position vertically under the head of the femur; for in that direction the leg not only supports the body with least effort, but it is also in that position that it can most easily avoid any impediment in its path by transferring the point of support to any portion of the sole of the foot, particularly if the latter be turned outwards, which gives a greater security than when it is directed parallel to the line of motion. The weight of the swinging leg and the velocity of the trunk serve to give the impulse by which the foot attains a position vertical to the head of the thigh bone; but as the latter, according to the laws of the pendulum, requires, in the quickest walking, a given time to attain that position, or *half* its entire curve of oscillation, it follows that every person has a certain measure for his steps, and a certain number of steps in a given time which in his natural gait in walking he cannot exceed. We can easily ascertain the time it requires to accomplish the quickest step in walking, which is equal to the half vibration of the leg made with relaxed muscles. In order to make the steps follow each other in much slower succession, the foot is not placed on the ground when it arrives in the perpendicular position, or the half oscillation from behind forwards as in the rapid pace, but we plant it on the ground somewhat later when the foot has described more than half the curve of vibration. From these principles we conclude that the man in *fig.* 255 walks much faster than that in *fig.* 256; in fact the former makes steps 27.559 in. in length, whereas in the latter the steps are barely 23.622 in. in length; and whereas the first makes a step in 0″.35, the second takes 0″.422 for a step, so that the velocity of *fig.* 255 is nearly double that of *fig.* 256. These figures are represented as walking on the toes, as if the foot always touched the ground in the same position, and their steps are shorter than when the entire sole is brought into action. *Fig.* 255 shows the greatest step which it is possible to make with the toes. The steps are shortest in *fig.* 257, in which the difference of the heights of the centre of gravity, compared with that of *fig.* 255, may be easily seen.*

In *figs.* 258, 259, and 260, the legs are of

* In these experiments the footsteps were taken on the ball only.

* These figures, with the others upon the same plan, reduced to $\frac{1}{20}$th the natural size, are drawn in accordance with the principles on which the theories of walking, running, and leaping are based. They are taken in the various instants of a step as seen through a revolving disc, constructed upon the principles of the stroboscope invented by Dr. Faraday, and modified so as to apply to these purposes by Stampher.† These

† Vide Poggendorff's Ann vol. 22. p. 600.

Fig. 255.

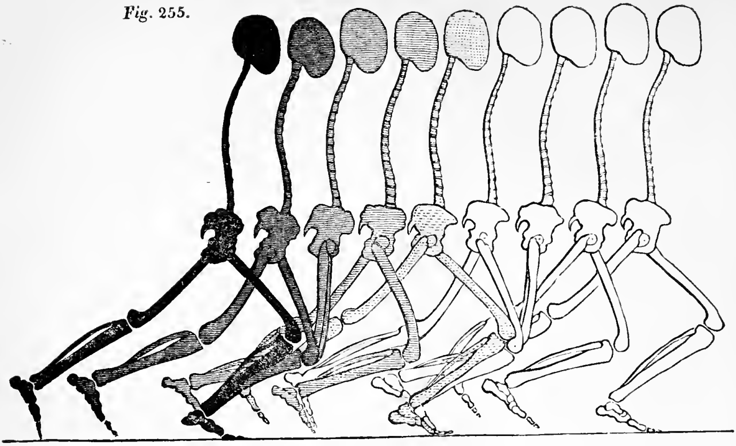

Fig. 256.

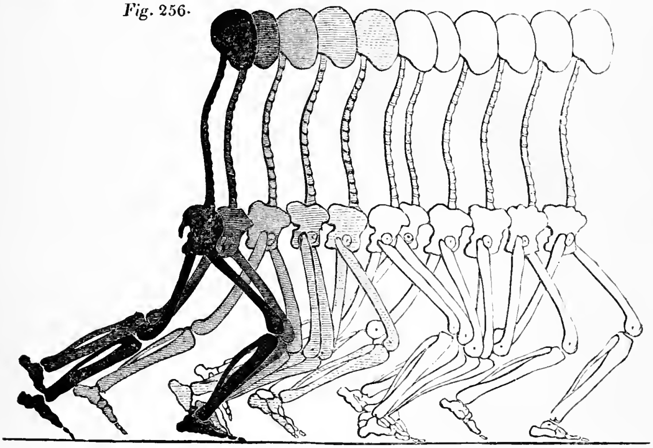

figures serve also to illustrate the following formulas.

$$h^2 + p^2 = l^2.$$

$$t - \tau = \tau \cos \frac{\pi}{T} t.$$

$$h = \frac{(\mu + 1) g}{\left(1 + \frac{\pi \tau}{T}\right)^2} \tau^2$$

These three equations, which are deduced from the general formulas, are intended to express the principal data upon which the theory of walking is based. If $n = r = 1$, and $\theta = o$, and we substitute for μ its value as deduced from experiment in walking, and let $(\mu + 1) g = 34.65$,† $T = 0''.7$ and $l = 0.95$ met. by substituting these values in the equations above we get the following results which accord very closely with experiment.

No.	τ	t	h	p
			m.	m.
1	0.″350	0.″350	0.642	0.700
2	0.414	0.372	0.727	0.611
3	0.422	0.375	0.736	0.600
4	0.432	0.378	0.749	0.585
5	0.446	0.382	0 765	0.564
6	0.465	0.387	0.786	0.533
7	0.494	0 395	0.817	0.484
8	0.542	0.406	0.864	0.395

Nos. 1 and 3 are represented in *figs.* 255, 256, and Nos. 1, 3, 7, in *figs.* 258, 259, 260.

† In this estimate $\mu = 2.53$, $g = 9.811$ metre.

equal length, equally extended, and represented at the moment when the previously swinging leg is placed on the ground; but *fig.* 260, which is walking slowly, has the leg advanced far beyond the vertical. *Fig.* 259, which is walking quicker, has the leg less advanced, whilst *fig.* 258, which represents the greatest possible celerity, has the foot placed directly in the vertical line, passing through the head of the femur. We observe also that of the paths described by the swinging leg of the three figures, that of *fig.* 260 has nearly completed the entire curve, that of *fig.* 259 a little more than half, and that of *fig.* 258 exactly half the curve; and that the dotted line which serves to indicate the path of the leg is least in *fig.* 260, greater in *fig.* 259, and greatest in *fig.* 258. The time is greatest in *fig.* 260, less in *fig.* 259, and least in *fig.* 258; consequently, when the leg swings beyond the

Fig. 257.

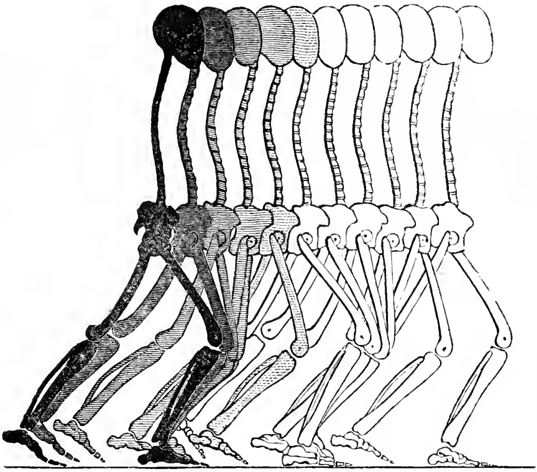

Fig. 258.

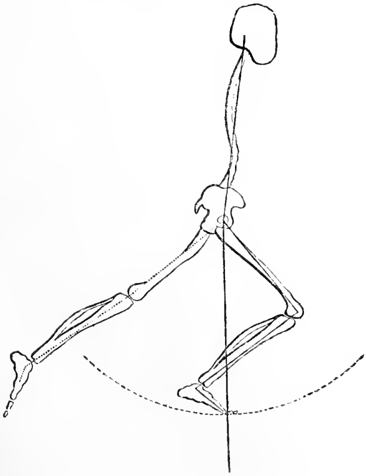

Fig. 259.

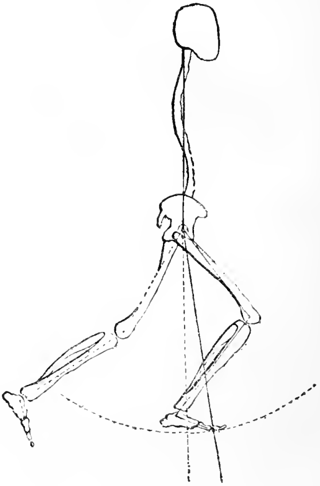

Fig. 260.

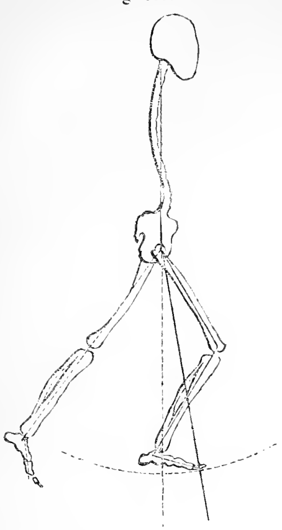
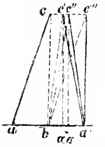


vertical line, not only the time of swinging the leg has increased, but also the time in which both legs are resting on the earth; for the latter commences at the instant when the forward leg has reached the ground, and terminates when the head of the femur has arrived at the vertical line, passing through the point of support of the same foot. The time augments in proportion to the distance which the swinging leg passes beyond the vertical position, or half oscillation. The time when both legs are resting is greatest in *fig*. 260, because it must be sufficiently great for the head of the femur, together with the whole trunk, to advance to a position directly over the foot, during which the head of the femur moves very slowly, and by the direction of the forward leg its action is to retard the horizontal advance of the centre of gravity. The time is less in *fig*. 259, because the head of the femur has to pass through a less space, and the supporting leg acts against the trunk at a less angle; but in *fig*. 258 the time of both legs resting at the same time, disappears altogether. The two legs complete the least portion possible of the vibrating curve, and the duration of each step amounts only to the time of half an oscillation. In walking very slowly we may suffer the swinging leg to vibrate so long, that it partly returns to its former position before it reaches the ground.

We have seen in quick walking that during the time both legs rest on the ground, the advanced leg continually forms a smaller angle with the vertical than the hinder leg; but in very slow walking the forward leg may form a greater angle with the vertical than the hinder leg; the magnitude of this angle determines the kind of gait the walker acquires. In order to accomplish this, the swinging leg is suffered nearly to complete its curve of oscillation before it is placed on the ground, and during this time the centre of gravity moves so little, that half the length of the step may not be at once described, and the entire duration of the step will be about four times greater than in the quickest pace.* In this case the forward leg really makes a greater angle than the hinder as it reaches the ground, but during the time that both legs are on the ground, the angle of the forward leg diminishes, whilst that of the hinder leg augments, and there is an instant when both legs form equal angles. When the angle of the forward leg becomes zero, or in other words, when it is directed vertically, the hinder leg rises from the earth; for example, in *fig*. 261, where $a\ c$ represents the right leg, $b\ c$ the left, in the beginning of a step, or the instant the foot a is raised from the ground; $c\ c'''$ is the magnitude of the step, or the space which the centre of gravity passes through in the time of a step, c'' being the centre of that space. Now, if the foot a, which was raised at the beginning of the step, were placed again on the ground at a', at the instant when the centre of gravity reaches the middle point c'', then both legs would form equal angles with the vertical; or, the angle $b\ c''\ \alpha = a'\ c''\ \alpha$, in which $c''\ \alpha$ is the vertical through c''; but if the angle of the hinder leg to the vertical be less, when the right leg is set down in a', the centre of gravity will not have arrived at the middle point c'', but at c'; however, whilst both legs are on the ground, the centre of gravity is propelled from c' to c'', after which the angle $b\ c'\ \alpha$ increases and the angle $a'\ c''\ \alpha$ diminishes (where $c'\ \alpha$ is the vertical through c'); when the centre of gravity is propelled onwards from c'' to c''', the angle $a'\ c''\ \alpha$ is less than $b\ c''\ \alpha$, until the termination of the step.

Fig. 261.



In this slow method of walking a very measured pace results, in which the body is carried very erect, and remains for a considerable time in the rear of the forward leg after it first reaches the earth; consequently the duration of the step will be very considerable, nearly one second and a half, the length of the step very short, and the velocity of the centre of gravity, which is very little at the middle of the step, varies considerably during each step, so that there is an instant in which the body is nearly at rest. This is denominated by Weber *the grave or procession step*.†

A remarkable difference may be observed in the duration of the steps of two different persons, one of whom has long and the other short legs. In quickest walking the duration of

* That is, where T represents the entire duration of an oscillation of the leg, the time of a step in the quickest to that in the slowest walking will be as $\frac{1}{2}$T to 2T, or four times that of quickest walking.

† Vide Weber, loc. cit. sect. 139, p. 344.

their steps will equal the time of oscillation, and the case is nearly the same in a slower pace. We observe, therefore, that when children and grown persons, or tall and little men, are walking together in the pace most easy and natural to them, they move in a different time. It is true the movements of the legs, like those of any other member, may be accelerated by means of the muscular force and made to move quicker than when they are merely impelled by their own gravity in swinging from behind forward, but when so continued an exercise of muscular power is required, such an unnatural pace cannot long be sustained.

In the estimate already given of the forces which have an influence in walking, it will be observed that as long as the force of the extension of the legs in a vertical direction upwards, is equal to that of gravity upon the body acting vertically downwards, the centre of gravity will move in a direction perfectly horizontal; but experience shows that as soon as the force of the extension of the supporting leg ceases, the centre of gravity falls below the horizontal path in which it was previously moving; but the instant the other leg stands perpendicularly it will rise again to its former level. The mathematical theory of walking proves that from the figure of the human machine there must of necessity be a sinking of the centre of gravity in order that progression may be accomplished. By varying the time of the sinking of the body at the end of each step, the effect of the resistance of the air and other extraneous influences which would disturb the horizontal velocity of the trunk, are compensated. In a favourable wind, when it travels at a greater velocity than the walker, it is necessary he should increase the time of sinking to counteract its effect, and preserve a mean uniform motion.

The application of mechanical principles does not accord with slow as it does with that of quick walking, for the former is too much under the control of the will of the walker, and the limbs are not suffered to swing freely by their own gravity as in quick walking, in which this volition diminishes, according to Weber, at least when the slightest exertion is continued for any length of time, and it is in this condition alone that theory and experiment nearly approximate. We must, however, remember that the control exercised by the muscular system over the limbs in slow walking is a new force which animals are enabled to interpose in order to vary the effects which result from the physical laws in operation during locomotion, and by no means refutes the theory of the influence of those forces which affect, not only the locomotion of animals, but the motion of matter universally.

Running.—The laws which regulate running in many of the lower animals, such as quadrupeds and birds, are nearly the same as in Man. It will therefore be necessary to enter into the details of this movement in reference to the latter only.

The principles upon which walking and running differ.—In running as in walking it may be considered as a fundamental law that the same motions of the body recur after each double step; and that both legs exercise equal and alternate actions in these movements. In running the object is to acquire a greater velocity in progression than can be attained in walking. In order to accomplish this, instead of the body being supported on each leg alternately, the action is divided into two periods, during one of which the body is supported on one leg, and during the other it is not supported at all. The latter condition constitutes the principal difference between these two modes of progression. When the body is projected upwards so as to swing freely in the air, the hinder leg must be raised from the ground before the advanced swinging leg has reached the vertical position; hence, in running, the duration of the step is less than the half-duration of the oscillation of the leg, because, when the advanced leg has reached the vertical position and is again placed on the ground, the hinder leg has already begun to describe a portion of its arc of oscillation. By these means the duration of the step is diminished, whilst the length is increased, both of which tend to augment the velocity. The length of the step is consequently greater than that side of a right-angled triangle, whose hypotheneuse is the extended leg, and the other side the elevation of the centre of gravity above the ground. In running the step may be divided into two periods; the first, the time t, during which the body is supported on one leg, and the second, the time $\tau - t$, during which it is not supported at all.

Forces employed in running.—The forces which act in running are the same as in walking; first, extension; secondly, gravity; thirdly, resistance. In running, a horizontal movement of the centre of gravity is not practicable as in walking, for although the extensor power might be so regulated that the centre should continue at the same elevation so long as the body poised on one leg, it would evidently fall during the time it was left unsupported. Now, as it is found after the whole time of a step to have neither sunk nor risen, and since no instantaneous elevation of the centre of gravity takes place between the termination of the preceding and the commencement of the following step; it follows that during the time t, it must ascend just as much as it sinks during the time $\tau - t$. The effects of gravity and resistance have been sufficiently explained in the theory of walking.*

The conditions for regular progression in

* By an analysis based on data similar to those for walking, Messrs. Weber have deduced the following equations which express the general laws of running.

$$(h + s)^2 + c^2 t^2 = l^2 \ldots \qquad (29)$$

$$(h + s - \tfrac{1}{2} g \theta^2)^2 + c^2 t^2 = l'^2 \ldots \qquad (30)$$

$$\tfrac{1}{2} T + \beta = 2\tau - t \ldots \qquad (31)$$

$$s = \tfrac{1}{2} g \frac{t}{\tau} (\tau - t)^2 \ldots \qquad (32)$$

running are fulfilled if the vital force which the body receives by the extension of the supported leg whilst it is on the ground, is equal to the vital force communicated to the swinging leg during the time of its oscillation.*

The motions of walking and running tend continually to approximate, in proportion as the time in which both legs are on the ground in the former, and the time in which the body is not supported at all in the latter, is diminished, and the laws of both running and walking coincide, when the time that the body swings unsupported in the air in the former, and that where both legs are on the ground in the latter, vanishes.

The resistance of the air to the trunk, when it is propelled with great velocity as in running, requires to be compensated, in order to be kept in a state of equilibrium, either by the force of its own gravity, or by that of its muscular system. The former method is usually adopted to prevent an unnecessary expenditure of vital power.

It will be seen in Table 4, that the angle of inclination of the trunk in running, is to that in quick walking, as 49°.8 to 31°.8, when the length of step in the former is to that in the latter as 1.509 to 0.888.

$$h = \frac{(\mu + 1)\, g\, (t - \theta)^2 \left(1 - \frac{2\, s'}{3\, h}\right)}{\left(1 + r\, n\, t\, \frac{\pi}{T}\right)^2 - (1 - r)^2} \quad \ldots\ldots (33)$$

$$r = \frac{g}{l}\, \frac{T^2}{\pi^2} \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (34)$$

$$s = \frac{t}{t - \theta}\, s' \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (35)$$

In which equations,

$$\theta = \frac{T}{\pi} \text{ arc } \left(\cos = \frac{1}{n}\right)$$

$$n = \sqrt{1 + \frac{r\,(h - s)^2}{l\, g\, t^2}}$$

The other expressions being the same as those in walking,

c .... is the uniform velocity of the point m in a horizontal direction.

s .... is the space through which the centre of gravity is raised in the time t.

s' .... is the space through which the same centre is raised in the time $t - \theta$.

When $\tau - t = o$, that is, in slowest running, the above equations become identical with those in quickest walking, where the time during which both legs are on the ground vanishes.

* That is, when

$$(m + m')\, \frac{g\, c^2\, (t - \theta)^2}{h} \left(1 - \frac{2\, s'}{3\, h}\right) =$$

$$m' \left(1 + r\, n\, t\, \frac{\pi}{T}\right)^2 c^2 - m'\, (1 - r)^2\, c^2$$

and as $\mu = \frac{m}{m'}$, by substituting μ, we get equation (33), from which the height of the centre of gravity is to be found.

In order to find the amount of the vertical undulations of the trunk in running, MM. Weber viewed the runner through a telescope, adapted for that purpose. They calculate the undulations to be from $\frac{3}{4}$th to $\frac{5}{4}$th of an inch; they estimate the duration of the step to be $\frac{1}{4}$th to $\frac{1}{5}$th of a second, of which the body swings freely in the air $\frac{1}{10}$th of a second, and of this falls $\frac{1}{15}$th; now, by the law of falling bodies, the centre of gravity will descend in this time 22 mm. = 0·85614 in.; hence, the body falls through a less space in running than in walking.

The simultaneous positions of the centre of gravity and of the two feet at individual instants of time, of which *fig.* 262 is a vertical, and *fig.* 263 a horizontal representation. The right foot is marked a, the left b, and the centre of gravity c: $b_{1\,2}$ signifies that during the time a is passing from a to a_2, and c from c to c_2, b remains standing on the point $b_{1\,2}$, and so on. In order to distinguish the swinging from the supporting leg, in *fig.* 262, the former is so contracted that it does not reach the horizontal line; and in *fig.* 263, the swinging leg is represented as if it swerved from the path both on the right and left sides alternately: c_1, $c_3 = c_3$, $c_5 = c_5$, c_7, indicate the length of the step $= p$, a_1, $a_{3\,4} = a_{3\,4}$, $a_{7\,8} = b_{1\,2}$, $b_{5\,6} = 2\,p$. The time which elapses from the instant when b steps in $b_{1\,2}$ to a, in $a_{3\,4}$, is the duration of a step τ. The time in which c advances from c_1 to c_2 is the time t, when the body is supported upon one leg. The time in which c advances from c_2 to c_3 is the time $\tau - t$, during which the body swings in the air. The time in which c advances from c_2 to c_5, is the time in which the left leg swings, which is greater than τ, in which c merely passes from c_3 to c_5. The instant when the left leg steps in b_1 or the right in a_3, the leg must press against the ground with such force as to impede the accelerating force of gravity upon the body, and communicate to it an ascending movement; to accomplish this, the leg must be set down on the ground perpendicularly, therefore the lines c_1, b_1, c_3, a_3, &c. are vertical.

The length of the extended leg being $b_2\, c_2$, *fig.* 262, at the end of the time t, $c_1\, d_1 = b_2\, d = c\, t$,* the horizontal distance of the body in the time t, and $c_2\, d = c_1\, b_2 + c_2\, d_1 = h + s$, where h represents the distance of the centre of gravity from the beginning of the step, and s the height to which it is elevated in the time t; now, if $b_2\, d\, c_2$ be a right-angled triangle, then

$$(b_2\, c_2)^2 = (b_2\, d)^2 + (c_2\, d)^2$$

or,

$$l^2 = c^2\, t^2 + (h + s)^2$$

That is, the square of the length of the extended leg is equal to the sum of the squares of the

* The line $c_2\, d$ is vertical, and $c_1\, d_1$ horizontal, meeting $c_2\, d$ in d_1; the letter d and line $c_1\, d_1$ are omitted in the figure to prevent confusion.

path described by the centre of gravity in the time t, and the distance of the centre from the earth at the end of that time. The time occupied in running between the raising of the leg from the ground and the setting it down again is equal to the duration of the step, together with the portion of time during which the body swings in the air; or, it is the time in which c (*fig.* 262) advances from c_2 to c_5, being the time between the raising of the left leg and the setting it down again, but this time is divided into two portions, namely, that whilst c

Fig. 262.

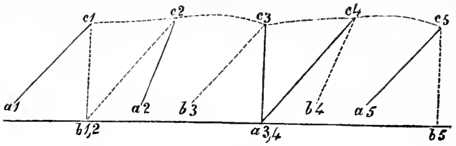


Fig. 263.

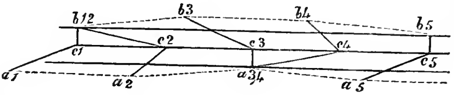

Fig. 264.

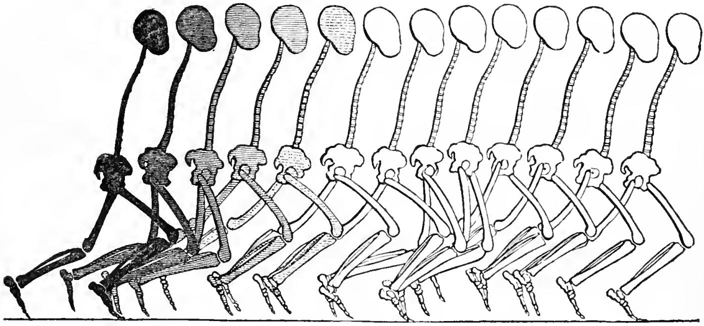
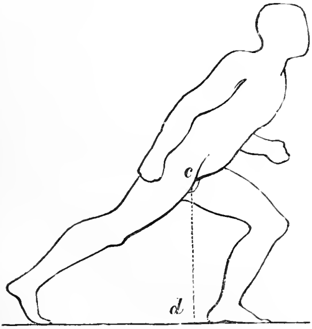


Figures designed by Weber, to illustrate the laws of running.

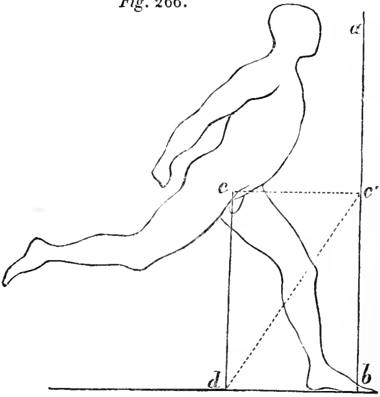
moves from c_2 to c_3, and that whilst it moves from c_3 to c_5; the latter portion is the duration of the step; the former the time in which the body swings freely in the air.

Fig. 265.



From these principles it is obvious that n man in the act of running could possibly be in

Fig. 266.



Preparing to run, and running, from designs by Flaxman. In fig. 265 c d *falls behind the advanced foot, so that the posterior leg bears only a small portion of the weight of the body, but is in a position to push the centre of gravity forwards before quitting the ground.*

the attitude of the annexed design by Flaxman (*fig.* 266), in which it will be seen that the whole mass of the body lies posterior to the vertical line $a\ c'\ b$, passing through the base of support, whereas the preceding theory shews that in quick walking and running the swinging leg never passes beyond the vertical $d\ c$, which cuts the head of the femur. This figure has therefore been drawn upon false principles.

TABLE 12.

A Table of fifty-six experiments on running with various velocities. Space passed through 43.43 *met.* = 142·2504 *feet.*

Number of experiments.	Mean Number of Steps.	Time.	Duration of Step.	Length in metres.	Velocity.
6	28·17	7″·56	0″·268	1·542	5·753
3	38·83	9·91	0·293	1·284	4·382
6	35·92	10·80	0·301	1·209	4·016
7	38·17	11·99	0·314	1·138	3·624
3	42 67	13·60	0·319	1·018	3·194
7	46·5	15·173	0·326	0·934	2·865
6	53·	16·81	0·317	0·819	2·583
8	60·5	18·35	0·303	0·718	2·369
5	71·2	21·68	0·304	0·640	2·105
4	83·75	25·45	0·304	0·519	1·707
3	104·33	31·84	0·305	0·416	1·367
3	137·7	41·49	0·301	0·315	1·046

From this table we see that the length of step increases rapidly, whilst the duration varies but very little; and that the duration is always equal to a half oscillation of a pendulum.

Duration of spring .. = 0·2618 } difference
Duration of half oscillation of pendulum } = 0·323 } 0″·0612

Hence we perceive that the duration of the spring is less than the oscillation of the leg as a pendulum by a very small fraction only, which is probably due to muscular action.

In quick running the length of step rapidly increases, whilst the duration slowly diminishes; but in slow running the length diminishes rapidly, whilst the time remains nearly the same. The time of a step in quick running, compared to that in quick walking, is nearly as two to three, whilst the lengths of the steps are as two to one, consequently a person can run in a given time three times as fast as he can walk. The velocity in running is usually at the rate of about ten miles in an hour, but there are many persons who for a limited period can exceed this velocity.

In the human race, however, the velocity in running varies considerably, depending on a variety of physical conditions, such as age, sex, stature, muscular power, the nature of the surface on which the progression is performed, and the angle of elevation above, or depression below the plane of the horizon. Man is exceeded in speed by many of the lower animals, owing to differences in the structure of the locomotive organs, and the physical laws which they obey.

Leaping or jumping.—This mode of progression is adopted by a great number of animals; some of which resort to it only for the accomplishment of a particular object, others as a regular means of locomotion.

In most of the orders of the animal kingdom there are some species which transfer themselves from place to place by a succession of impulses, in air, in water, and on solids: it is to the latter we shall confine our attention, having already briefly mentioned the former in the sections on flying and swimming.

In leaping, the object to be attained is to take the greatest length of step without reference to its duration; and herein it differs from running, in which the greatest steps are taken in the least possible time.

The height to which animals of different orders are capable of springing * varies, but, according to Straus-Durckheim, all those in the same order leap to equal elevations.

Amongst insects, the Grasshopper and Cricket, and in the order Felis, the Cat, the Leopard, and the Tiger, all rise to the same elevations above the positions of their respective centres of gravity at the instant when their feet quit the ground.

This appears at first to be inconsistent with the computations made on the proportion of the force of muscles to the mass of animals of different dimensions. If we select four different animals of the same order, in which the dimensions of one kind are as 1, 2, 3, 4, their weights will be as the cubes of these numbers, or, as 1, 8, 27, 64; but since the force of a muscle depends on the number of its fibres, and therefore increases in the ratio of its transverse section; that is, as the square of one of these dimensions, the muscular forces of the animals will be as 1, 4, 9, 16, and the velocities (supposing the muscles to act instantaneously) will be as the forces divided by the weights, or as 1, $\frac{1}{2}$, $\frac{1}{3}$, $\frac{1}{4}$, and the heights of the leaps being as the squares of the velocities would be as 1, $\frac{1}{4}$, $\frac{1}{9}$, $\frac{1}{16}$. Now, as they are all found to arrive at the same height, this may be explained by supposing that the muscles do not act instantaneously, but as constantly accelerating forces during the continuance of the spring. The force on an unit of mass in the Cat is to that on an unit in the Tiger, as 1 to $\frac{1}{4}$; and since the dimensions of the latter are four times those of the former, the tiger passes through four times the space the Cat passes over, reckoned from the beginning to the end of the time the muscles act, until the animal quits the ground, and therefore is elevated to the same height as the cat.†

From these principles we see the reason why

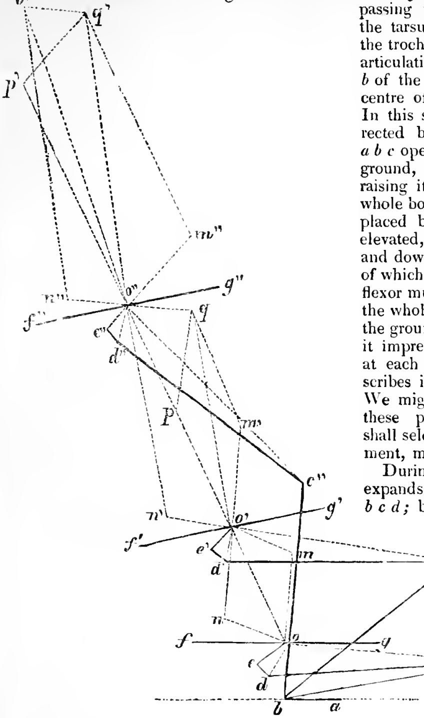
* The spring is that portion of the leap which takes place before the feet quit the ground.

† Thus:—Let s = the space passed through during the spring of the cat, f = the muscular force employed in the time t of a spring, then, by equation (3),

$$s = \tfrac{1}{2} f\, t^2.$$

Now, as the tiger passes through a space = $4s$,

Fig. 267.



many of the small insects leap a greater distance in proportion to their masses than the larger animals; for example, if the Flea, which can leap two hundred times its own height, were as large as the Cricket, it could only leap as far as it does at present; but the latter can leap much higher than the former, and therefore, of these two insects, the Cricket is the best organized for leaping. We shall now proceed to investigate the effect of the extension of the legs of insects in leaping.

and the muscular force equals $\frac{1}{4} f$, during the time t' of its spring,

$$\therefore 4s = \tfrac{1}{2}\frac{f}{4}t'^2 \quad \ldots\ldots\ldots\ldots\ldots\ldots (36)$$

and,

$$t' = 4t. \quad \ldots\ldots\ldots\ldots\ldots\ldots\ldots\ldots (37)$$

The velocity of the cat will be,

$$v = \sqrt{2fs}$$

hence, that of the tiger is,

$$v' = \sqrt{2\frac{f}{4}\,4s} = \sqrt{2\,fs}$$

that is, the tiger and cat have the same velocity, and therefore the same height of spring, reckoned from the positions of their centres of gravity at the instant of their quitting the ground.

Let $f\ g$ (*fig.* 267) be the axis of the body, passing through the centre of gravity o; $a\ b$, the tarsus; $b\ c$, the leg; $c\ d$, the thigh, with the trochanter; and $d\ e$, the hip. All these articulations being flexed, the tarsal extremity b of the leg is advanced forwards under the centre of gravity o, which is a little above it. In this state, if the tarsus $a\ b$, which is directed backwards, become flexed, the angle $a\ b\ c$ opens, and as the tarsus rests against the ground, the leg $b\ c$ begins to move, and raising its crural extremity, draws with it the whole body. Now, as the centre of gravity is placed before the point b, instead of being elevated, it is, on the contrary, urged forwards and downwards, describing an arc of a circle, of which the centre is b, and the action of the flexor muscle of the tarsus continuing during the whole time that the limb is resting against the ground, the direction of the motion which it impresses on the centre of gravity changes at each point of the arc which the latter describes in being always a tangent to this arc. We might thus determine its action for each of these points, but for greater simplicity we shall select only three; namely, the commencement, middle, and the end of the motion.

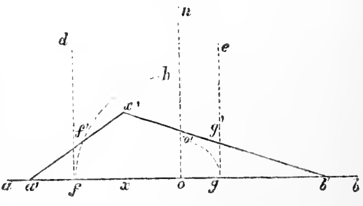
During the flexion of the tarsus, the leg expands itself, and tends to open the angle $b\ c\ d$; but since it rests with its tarsal extremity upon the plane of position, the thigh $c\ d$ becomes moveable, and is raised forwards, turning as a radius round its cruro-tibial articulation c, and carrying with it the whole body, in the same manner as in the motion of the leg; the direction of the force produced by the extensor muscle changes at each point of the curve which the centre of gravity describes; but this direction is always a tangent to the curve, and consequently perpendicular to the radius $c\ o$, passing through the cruro-tibial articulation and centre of gravity. The motion produced by the extensor muscle of the trochanter on the thigh $c\ d$, opens the angle $c\ d\ e$, tending to depress it at its tibial extremity, but as it rests upon the leg, which by its own elevation resists it, the motion is wholly communicated to the hip $d\ e$, which is flexed forward, and carries the body with it; the direction of the force of this muscle is perpendicular to the radius $d\ o$, passing through d, the articulation of the hip with the trochanter and the centre of gravity. Lastly, the motion produced by the extension of the hip $e\ d$ upon the body in a direction opposite to that of the thigh, is perpendicular to $e\ o$, and impresses on the centre of gravity an oblique impulse downwards and backwards. The forces resulting from the extension of the tarsus and the hip being very feeble, may be neglected.

The muscular force expended in these motions may be thus approximatively estimated. By the extension of the leg, the centre of gravity o will be acted on at the beginning of motion by a force $o\,m$ perpendicular to $o\,c$; by the extension of the thigh at the same time the centre will be also urged by a force $o\,n$, perpendicular to the radius $o\,d$; the resultant of these two forces is $o\,o'$, in the direction of which the centre of gravity is raised in the first instant of motion, and the body and foot will be in the position $a, b, c', d', e', o', f', g'$. If the action of the muscles ceased after this first impulse, the body would arrive in the second instant at p, where $o'p = o\,o'$, but at the point o' the centre of gravity receives two new impulses, one $o'\,m'$ from the extensor of the leg, and another $o'\,n'$ by the extensor of the trochanter; the first is in a direction perpendicular to $o'\,c'$, the second perpendicular to $o'\,d'$, the former being combined with the motion $o'\,p$, which is that of the centre of gravity; in the second instant there arises a second resultant $o'\,q$, which the body would pass through in the second moment, if the action of the thigh did not take place, but this new force $o'\,n'$ being combined with $o'\,q$, produces the ultimate resultant $o'\,o''$, which the centre of gravity really passes through in the second moment, and the body takes the position $a, b, c'', d'', e'', o'', f'', g''$. In the moment which follows, the centre of gravity would arrive by the second impulse at p', a distance equal $o'\,o''$, but the forces of the muscles continuing to act, one of them $o''\,m''$ produced by the extensor of the leg, and always perpendicular to $o''\,c''$, gives with the motion $o''\,p'$ a resultant $o''\,q'$, which being combined in its turn with a force $o''\,n''$ produced by the extensor of the trochanter in a direction perpendicular to $o''\,d''$, gives a new ultimate resultant $o''\,o'''$, which the centre of gravity passes through in the third instant. If the distance from the point o''' to the point b is greater than the length of the leg, it is evident that the body of the insect will be elevated during the third instant, and the muscles being no longer able to produce any new impulses, because the foot no longer furnishes them with points of support, the centre of gravity will in the succeeding intervals of time pass over spaces equal to $o''\,o'''$.

In this demonstration we have only considered two forces as acting to produce the leap, but there are others which influence the motion of the body as above mentioned, the effect of which we must here notice. By the extension of the hip on the thigh, the body which we have supposed not moveable on the hip would be flexed forwards from its horizontal position; but this is corrected by the motion of the body on the hip and by that of the leg on the tarsus. The extensor muscle of the tarsus opens the angle $a\,b\,c$, and tends to lower the extremity a of the tarsus; but since that is supported the leg $b\,c$ is moved and flexed upwards, giving to the centre of gravity a motion forwards and downwards, perpendicularly to the radius $b\,o$. This new force being combined with $o\,o'$, produces in the first instant a resultant more inclined forwards than $o\,o'$. This oblique direction is afterwards corrected by the motion of the body on the hip. In short, if the body were only subject to the forces of the muscles of the tarsus, the leg, and the thigh, it would take a direction more oblique than $f'\,g'$; but by the motion of the body on the hip, the centre of gravity receives a new impulse backwards and downwards perpendicular to $e\,o$, and this new force combined with $o'\,o''$ gives a resultant more vertical, and as it acts in an oblique direction downwards, it diminishes necessarily the velocity of the leap; but the body thereby regains its horizontal position. The other legs also contribute to the elevation of the body in leaping, but their action must be very feeble, because these limbs seldom present a greater size or force in leaping insects than in other species. The middle pair of legs being always directed outwards and backwards, urge the body upwards and forwards. The anterior pair, on the contrary, being placed greatly in advance of the centre of gravity, and directed opposite to the others, move it upwards and backwards; these limbs, however, being comparatively very feeble, can produce but little effect on the direction which the body would take were it only impelled by the two hinder pairs.

In almost all the perfect insects the legs are the instruments of leaping, but the Elater is capable of jumping whilst on its back, in order to recover its normal position, which owing to its figure it could not otherwise effect. For this purpose, a mechanism not generally found in other insects is provided; the *pro-sternum* is prolonged backwards, and terminates in a strong conical spine, which in a state of repose is lodged in a grooved cavity situated in the *meso-sternum*. The insect having been turned on its back, is observed to curve the body forcibly backwards; during this movement the spine of the sternum is drawn out of its sheath, and rests upon the edge of it, and the bases of the elytra are elevated above the plane of position. The flexor muscles, situated on the inferior aspect of the body, next contract, by which the spine is forcibly pressed against the edge of its sheath; the sternum is then suddenly relaxed, the spine darts into its sheath with great velocity, the head and thorax fly up, and the base of the elytra descends upon the supporting surface with such force that the insect by the reaction is propelled upwards to the height of one or two inches, during which the animal turns over upon its legs. In order to understand more clearly how this takes place, let $a\,b$ (*fig.* 268) be the axis of the body; o its centre of gravity; x the articu-

Fig. 268.



lation at which the trunk and thorax are flexed upon each other; *f* and *g*, the centres of force of the anterior and posterior parts of the body; when the body is curved preparatory to the leap, it takes the position $a' x' b'$, and the centre of gravity will be at o'; when the body returns to its former position $a\ x\ b$, the two centres of force come in contact with the ground in *f* and *g*; the forces with which they strike the ground acting perpendicularly to $a\ b$, impart to the centre of gravity *o* a velocity in the same direction, but the reaction of the ground gives to the body two impulses equal and opposite to the forces $d\ f$ and $e\ g$; the lines $f\ d$ and $g\ e$ not passing through the centre of gravity *o*, one part only of the force raises the body above the ground, the other part of the force produces a rotation of the body around the centre of gravity; the force $g\ e$ being much nearer the centre than $f\ d$, and their velocity of rotation being in the direct ratio of their distances from the point *o*, the motion produced by $g\ e$, being opposite to that of $f\ d$, is destroyed by a part of the latter, and the remainder of $f\ d$ will give the body a rotatory motion in the direction of $f\ f'\ h$: by means of this motion the insect is enabled to reverse its position.* The larvæ of insects are variously organized; for example, that of the Tyrophaga casei, when preparing to leap, bends itself into a circle, bringing its head and tail in contact, and fixing its two mandibles in the cavities of its anal tubercles; it then contracts its body into an oblong figure, so that the two halves are parallel to each other. This being accomplished, it suddenly unlocks its head, and extends its body with such force, that the reaction of the surface on which it rests propels the body into the air to the distance of several inches. The leaping of fishes and serpents has been already mentioned in Section IV. Birds walk, run, and leap like Man. The Incessores and other short-legged Birds usually move on solids by a succession of leaps.

In most quadrupeds the propelling force of the leap is produced by the extension of the posterior extremities alone. When a considerable elevation of the body is the object to be attained, the centre of gravity is, previously to the leap, thrown back and lowered by the flexion of the hip, knee, and ankle-joints of the hind legs; the fore-legs are then raised from the ground by the extensor muscles of the trunk, the axis of which, before parallel to the horizon, is now inclined at a considerable angle to it. At this moment the extensor muscles of the posterior extremities are suddenly contracted, and the leg is extended with sufficient velocity to elevate the trunk of the animal above the ground. At the end of the leap, the anterior feet first reach the ground simultaneously, and then the two hind feet in a similar manner; the head being brought between the two fore-legs, in order to throw the centre of gravity as far back as possible. The direction of the force of propulsion depends on the position of the propelling legs, and on the angle of inclination of the trunk to the plane of motion;—the intensity on the quantity of force impressed by the extension of the legs. In those quadrupeds which constantly move by a succession of leaps, the length of the posterior legs greatly exceeds that of the anterior; but in those wherein the length of the four legs is nearly equal, the leap is attended with so great an expenditure of muscular action that it is only resorted to on particular occasions.

Borelli* is of opinion that the power of leaping is greatest in those animals in which the extremities of the bones of the legs describe (in proportion to their masses) arcs of greatest circles, because they must move with greater velocity in the same time; in other words, that those animals which have the greatest relative length of the posterior legs leap to the greatest height. Nor does this militate against the analysis of Straus, according to which we have seen that animals of the same kind which have the greatest length of leg occupy a proportionably long time in springing.

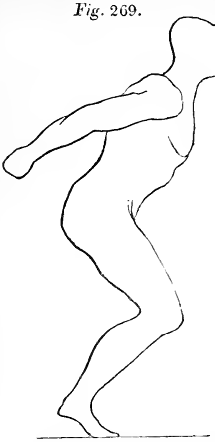
In the Bull-frog amongst the Batrachia, in the Kangaroo amongst the Marsupialia, and in the Jerboa amongst the Rodentia, we find the greatest disproportion in the length of the anterior and posterior extremities; the length of the latter predominating so greatly, that they walk and trot with difficulty; but when pursued, the Jerboa can leap nine feet at each step, and repeat these leaps so rapidly, that it is said the Cossacks, though mounted on the fleetest horses, cannot overtake them. The Kangaroo reposes on the hind legs and tail, which form a triangular base, leaving the arms free for prehension. Independently of the Jerboa, other Rodentia, such as the Hare and Rabbit, are also furnished with lengthened posterior extremities, by which they possess considerable power of springing. As the mass of animals increases in a greater ratio than the force of their muscular system, the large Proboscidiæ are almost incapable of leaping, but the solidungulous Pachydermata are well organized for leaping, as well as many of the Ruminantia, such as the Deer and Antelope. In these two orders the lengthened calcaneum and metatarsal bones contribute chiefly to assist the muscles in the spring. In the Carnivora, we find the ankle-joint possessing the same structure as in the Ruminantia and Pachydermata. The geometrical relation of their osseous and muscular systems is such as to confer on them great power in making a spring; that of the Tiger is well known. The leaping of the Cheiroptera and Quadrumana

* According to Kirby and Spence (loco cit. vol. ii. p. 314), the elater makes a double movement preparatory to the leap, by first drawing out the spine from its sheath, making it re-enter, and then causing it to fly out with a spring in the moment of leaping. This, however, appears to be a very incorrect view of what takes place. Mr. Darwin does not consider that sufficient stress has been laid on the elasticity of the spine, and that the sudden spring of the elater could not have resulted from muscular contraction alone, without some mechanical contrivance. (Journal of the Voyage of the Beagle, vol. iii. p. 35.)

* Quò longiores sunt vectes extremi crurum, saltus majores fiunt. See Part. prim. Prop. 176, p. 211.

has been briefly described in the last section, and our limits will not permit further illustrations. We shall therefore proceed to the investigation of the leap in the human race.

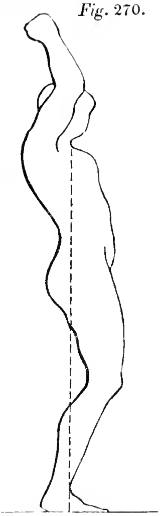
Fig. 269.



Preparing to leap with both legs, as designed by Flaxman.

In Man the leap is accomplished with considerable expenditure of muscular action, amounting, according to Borelli, to no less than 2900 times the weight of the body;* but since, notwithstanding the increased exertion, the velocity of this kind of motion is much less than in running, it is rarely adopted as a means of continued progression, but rather for passing over the greatest possible space without regard to the time taken to accomplish each step. In leaping, either both legs are employed simultaneously to project the body, as in *fig.* 269, or each leg is used alternately. Borelli has confined his observations to the former case; but as that mode of leaping merely consists of a succession of isolated movements, there being always a pause between each two, we shall investigate the latter case as the only one which admits of a continued uniform progression, the only one, therefore, which is properly within the scope of the present article.*

Fig. 270.



Position of the body at the termination of a leap with both legs.

* This estimate is calculated by Borelli in the same manner as the force of the muscles in Section I. On this, as on several other occasions, Barthez has chosen to deny without attempting to disprove the conclusion of Borelli. (See Barthez, Nouv. Mecan. p. 97.)

In the alternate movement of the legs, the swinging leg is not placed on the ground as soon as it has reached the vertical position, as in quickest walking and running, but it is suffered to swing beyond it, and the placing it on the ground is delayed until it comes a second time to the vertical position, consequently the body swings freely in the air for a longer period than in running, whereby a longer step is effected. *Fig.* 271 represents the various positions of the centre of gravity and of each leg in successive instants of time: a is the right foot, b the left, and c the centre of gravity. $a_{1\,2\,3}$ signifies that while c moves from c_1 to c_2 and c_3, and b from b_1 to b_2 and b_3, a remains at the point $a_{1\,2\,3}$. The spaces $a_{1\,2\,3}$, $b_{4\,5\,6} = c_2$, $c_5 =$ &c. the lengths of the steps. It will be observed that whilst the body is advancing from c_1 to c_3, it is supported and projected by the right leg. From c_3 to c_4 both legs are off the ground, from c_4 to c_6 the body is supported and projected by the left leg, and from c_6 to c_7 both legs are again off the ground, and so on successively.

TABLE 13.

Table shewing the length and duration of the steps in leaping with various velocities.

Length of steps.	Duration.	Velocity.
1.243	0.460	2.702
1.578	0.468	3.372
1.688	0.455	3.710
1.809	0.411	4.402
1.977	0.404	4.894

* In leaping, the equations (29) (32) (34) are the same as in running. Equations (30) and (35) are omitted, for $\theta = o$, since the centre of gravity of the body does not sink, because at the beginning of each step the leg is bent, and there is, therefore, no depression, as is necessarily the case in walking and running. Instead of equations (31) and (33), we have,

$$2\tau = T + \beta + \left(1 + \frac{1}{\cos\frac{\pi}{T}\beta}\right) t \quad \ldots\ldots (38)$$

$$h = \frac{(\mu + 1)\, g\, t^2 \left(1 - \frac{2s}{3a}\right)}{r\,(2 - r)} \quad \ldots\ldots\ldots (39)$$

The condition for regular progression in leaping, as in walking and running, is that the vital force communicated by the supporting leg to the trunk, equals that communicated by the trunk to the swinging leg. In the present case the latter force is,

$$m'\, c^2\, r\,(2 - r) \quad \ldots\ldots\ldots (40)$$

and the former is the same as in running.

By table 13 we find that the duration of the step in leaping is less than in slow walking,* but greater than in running;† the length of step is much greater than in walking, and may be made greater than in quickest running. As the body swings freely in the air a longer period, and rises to a greater elevation in leaping than in running and walking, it is necessary that the projectile force should be made greater, but the time during which the extensor power of the leg acts, although very short, is of intense action; hence, it is not easy to regulate the amount of muscular action as in walking and running, and consequently it may be too great or too little for the object in view. The vertical undulations also are much more considerable than in the other modes of locomotion.

Fig. 271.

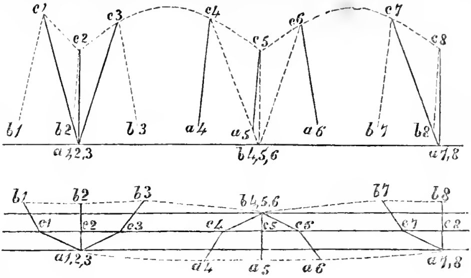


Fig. 272.

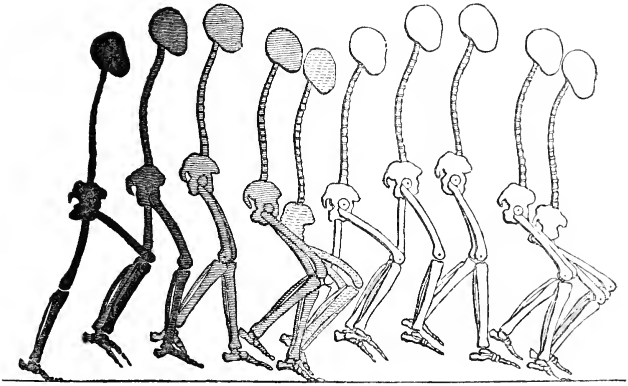

Figures designed by Weber to illustrate the formulas for leaping.

In descending rapidly the sides of steep hills it is much safer to do so by leaping than by running, as in the former mode of progression the foot is placed on the ground at the end of each step in a position favourable for stopping, which cannot be done in the latter. MM. Weber consider that the study of the laws which regulate the locomotion of man, and of the mechanism by which it is accomplished, will assist mankind in the construction of automatic locomotive machines. Mr. G. Rennie has studied the construction of animals and the principles on which they move with a view of applying them to the locomotion of the steam-boat, on the supposition that animals move in air, in water, with the least expenditure of muscular force, an hypothesis which accords with our views as well as those of M. Dumas, who considers that man is capable of moving and producing a greater mechanical effect, with less expenditure of fuel, than can be produced by any steam-engine hitherto invented.

In every mode of progression there is a sensible increase of action in the circulating and respiratory systems; but the effect produced on them is much greater in running and leaping than in walking. In the two former cases a violent palpitation of the heart and hurried respiratory movements are quickly produced, on which account they cannot be very long continued. In running, when four steps are taken in a second, the difficulty of breathing soon causes the pedestrian either to slacken his pace, or what may be most advantageously substituted when it is desirable to continue nearly the same speed, and at the same time preserve the breath, to exchange the running for a leaping movement. In consequence of the deliberate manner in which the steps may be taken in leaping, the breath may be preserved for a longer period, and the action of the heart diminished;

* See Table 8. † See Table 12.

and as the lengths of the steps are greater in leaping than in running, the velocity is not very sensibly diminished, although the duration of each step is increased; that is, for example, when we substitute three leaping, instead of four running, steps in a second. In Table 12 we find that the greatest length of step in running is 1m.512, and in Table 13 that the greatest length of step in leaping is 1m.977, consequently four of the former exceed three in the latter mode of progression in a second by 0m.237, or 0.76736 feet only; but this loss of space is compensated by the greater time the pedestrian employs in taking each step in leaping, being = 0″.136.

MM. Weber consider that leaping stands in the same relation to running that the grave step in slow walking does to quick walking. The difference of the grave and quick step in walking consists in this, that in the former the oscillation of the leg has nearly completed its curve of vibration before it is placed on the ground, and therefore forms a greater angle with the vertical than the hind leg. The same difference also exists between running and leaping, independently of which there is another important variation, which is that in leaping the swinging leg completes its entire arc of vibration before it is placed on the ground, and makes the greatest angle with the vertical it can possibly effect. In running, on the contrary, the leg is set perpendicularly on the ground and consequently the angle with the vertical $= o$. In the grave step as well as in leaping the foot is brought into contact with the ground preparatory to resting upon it; and, lastly, the duration of the leaping step exceeds that of the running step in the same degree that the duration of the grave step exceeds that of the quick step. These are the principal differences which distinguish the four modes of locomotion most usually adopted by man.

The study of the mechanism of which the locomotive organs of animals is composed, of the laws by which their progression is accomplished, and of the vital force which they expend in propelling the body from one point in space to another with different velocities, serves to instruct alike the anatomist and the physiologist, the artist and the mechanician. Ignorance of these laws has been productive of grotesque delineations of the human figure as well as of the lower animals when represented in motion. We have abundant evidence of this in the productions of painters and sculptors, both of the ancient and modern schools. Locomotion is not only a function indispensably necessary for the prolongation of the lives of a vast assemblage of animals, but it is also applicable as a force to innumerable purposes in life. On account of the importance of this subject, we shall in conclusion briefly investigate the manner in which animal force is estimated, and under what circumstances it may be employed to the greatest advantage. Thus, let φ denote the whole force of an animal when at rest, and let us suppose it to be incapable of any effort when it is moving with the velocity V; let F be the effective force when its velocity is V′; then, if the action of the force be uniform, (which from the principles assigned we may consider to be the case,) since it is the difference only between the velocities V and V′ that is efficient, the effective force will vary as the square of the efficient velocity, that is

$$\varphi : F :: (V - o)^2 : (V - V')^2$$

$$\text{hence } F = \varphi\left(\frac{V - V'}{V}\right)^2 = \varphi\left(1 - \frac{V'}{V}\right)^2 *$$

$$\text{and } V = \frac{V'\sqrt{\varphi}}{\sqrt{\varphi} - \sqrt{F}} \quad \ldots\ldots\ldots \quad (41)$$

or, the utmost velocity with which any animal not impeded moves, is to its velocity when impeded by a given resistance, as the square root of its absolute force to the difference of the square roots of its absolute and effective forces. Let us now investigate the velocity with which an animal must move and what must be its load, that the work performed by it may be a maximum. Retaining the same notation, let $V - V' = u$; then since $F = \varphi\frac{(V - V')^2}{V}$ the product of the moving force into its velocity, or the momentum of impulse FV′, will $= \varphi\frac{u^2}{V^2}(V - u)$, and making this a maximum, we find $u = \frac{2}{3}V$, and $V' = \frac{1}{3}V$. Therefore the effective work of an animal is a maximum when it is so loaded, that with its whole force in action its velocity amounts to one-third of the greatest velocity which it is capable of exerting without any load at all. In a series of experiments made on men and horses, by drawing a lighter along a canal, and working several days consecutively, the force was measured by the curvature and weight of a track rope, as well as by a spring steelyard; and the product of this force multiplied by the velocity per hour was considered as the momentum. By these experiments the forces of men were found very nearly as $(V - V')^2$, and those of horses, loaded so as not to be able to trot, as $(V - V')^{1.7}$ to $(V - V')^{1.8}$, results which agree very closely with the theory. In the application of these formulæ let us suppose a man's power to be 70 pounds, and his utmost speed in walking to be six feet per second, hence φ will equal 70, and V equal 6, therefore $F = \frac{4}{9}\varphi = 31\frac{1}{9}$, which is the greatest force a man can exert in walking, and he will move at the rate of $\frac{1}{3}V = 2$ feet in a second.† The strength of a horse may be easily computed in a similar manner—it is generally reckoned to be six times that of man, or about 420 pounds at a dead pull—then its

* This is a formula of Euler's, who has given another expression $\varphi\left(1 - \frac{V'^2}{V^2}\right)$: by this formula the greatest mechanical effect is when $V' = \sqrt{\frac{1}{3}}\,V$, but it does not agree with the experiments of Schulze and others as near as the one in the text See Schulze *on the Strength of Men and Horses, Acad. Berl.* 1783.

† According to Buchanen, the force expended in pumping is 1742, by a winch 2856, in ringing 3883, and in rowing 4095.—Buchanen on human labour, Repert. 15, 319.

velocity being about 10 feet per second, its maximum action will be $\frac{4}{9}$ (420) = 185$\frac{2}{3}$, and it will move at the rate of $\frac{10}{3}$ or 3$\frac{1}{3}$rd feet per second, being about 2$\frac{2}{5}$ miles per hour. With the help of these formulæ the maximum forces of any other animals may be found.

(John Bishop.)

MUCUS (from μυξα, the secretion of the Schneiderian membrane). This word has been used in so very indefinite a sense by the members of the medical profession, that animal chemists have had great difficulty in fixing on any distinctive characters by which the substance might be identified. The great source of confusion appears to have been that physiologists and the profession generally have applied the adjective mucous or mucoid to certain forms of secreted matter; from which circumstance the term mucus has gradually advanced into substantive use as a medico-chemical word, embracing in its meaning the secretions from the mouth, nose, intestines, &c. as though these were identical in their chemical characters. We shall presently show, however, that such is not the case.

In the Philosophical Transactions for 1800 Mr. Hatchett published a paper, in which he endeavoured to show that such a principle as mucus really existed, characterised by peculiar properties; but considered it a modified form of gelatin. Dr. Bostock subsequently published a paper in Nicholson's Journal, in which he showed that mucus differed from gelatin; this he proved by demonstrating that tanning did not precipitate mucus, though gelatin was immediately thrown down by it, whereas diacetate of lead precipitated mucus copiously, without affecting gelatin: bichloride of mercury and ferrocyanuret of potassa did not precipitate either mucus or gelatin. I shall show hereafter that these last-mentioned reactions do not apply to every form of mucus: the ingenious experiments of Dr. Bostock can indeed no longer be considered pertinent, inasmuch as the researches of modern chemists have gone far to prove that gelatin is rather a product than an educt of animal analysis. The experiments of Dr. Bostock were made on the saliva of the mouth, and some subsequent observations by Mr. Brande made on the same secretion showed that the precipitates obtained by the diacetate of lead and nitrate of silver consisted of the chlorides and phosphates of those metals; a fact which inclined Mr. Brande to consider mucus as a compound substance rather than a proximate element, and induced him to apply electricity as a means of decomposition. From the results obtained in this inquiry, Mr. Brande was inclined to consider mucus as a compound of albumen either with pure soda or chloride of sodium.

Dr. Marcet made some experiments on mucus which induced him to believe that several morbid secretions contained it as a constituent; he considered it to be present in dropsical effusions. Berzelius, though he allows the secretions of the mucous membranes to differ in chemical character, and to possess distinct properties according to the especial office they have to fulfil in lubricating particular parts, still believes that such a proximate element as mucus really exists as one of the constituents of such secretions, and notices it in his analysis of mucus of the nose. In considering this subject it is, therefore, necessary to premise that the general term, as used by the medical profession, has no relation whatever to the chemistry of the question, the secretions of the different mucous membranes varying greatly in chemical composition, but, notwithstanding, presenting a physical character in common, in relation to which the term mucous has been applied to them. The inquiry of greatest interest consists in determining whether there exists a peculiar proximate element in virtue of which the mucous character is developed, or whether, on the other hand, the peculiar physical character can be traced to the presence of some combination of albumen which is common to all mucous secretions, notwithstanding that they may differ greatly in other respects. We have already seen that the latter opinion is supported by Mr. Brande's experiments, while Berzelius, on the contrary, seems to favour the former view of the case. Before entering upon this question I shall describe the chemical characters of several secretions from mucous surfaces, as the reader will then be better prepared for the inquiry. I shall commence with the secretion from the nose, since this may be regarded as the type of those viscous products to which the general name of mucus has been applied.

The secretion of the Schneiderian membrane, according to the analysis of Berzelius, is composed as follows:—

Mucus	5.33
Alcoholic extractive and alkaline lactate	0.30
Chlorides of potassium and sodium ..	0.56
Aqueous extractive, traces of albumen, and a phosphate	0.35
Soda, combined with the mucus	0.09
Water	93.37
	100.00

The chemical characters of the substance which Berzelius notices in this analysis as "mucus" are as follows. It is not soluble in water, but swells up and becomes transparent. When dried it is again capable of being swelled by water; but after this experiment has been repeated several times it becomes of a yellow colour, and assumes somewhat the appearance of pus. When boiled in water it neither hardens nor contracts; but after this treatment it is found, to a certain extent, to have lost its property of swelling. When dry it is of a yellow colour and transparent. By distillation it yields carbonate of ammonia and empyreumatic animal oil. The ashes obtained from this substance yield phosphate and carbonate of lime, with traces of carbonate of soda. This mucus is soluble in weak sulphuric acid; the strong acid darkens its colour and eventually destroys its texture. Weak nitric acid coagulates it superficially and renders it partially yellow: long digestion in this acid causes its solution. Acetic acid contracts it, but does not dissolve it even when assisted by heat. It dissolves from it, however, a portion of albumen, which renders the solution precipitable by the ferrocyanuret of potassium. Caustic potash renders this mucus more tenacious, but by digestion it dissolves it. Infusion of galls coagulates it when dissolved in acids or when swelled by water. These characters described by Berzelius may be received as the general properties of that substance to which mucous secretions owe their viscous character.

Urinary mucus.—This form of mucus is best obtained by allowing recently voided urine to remain at rest in a tall glass vessel, when the mucus will subside after some hours, and may be collected by pouring off the supernatant fluid as nearly as possible without disturbing the precipitate, and throwing the remaining part of the secretion on a filter; the mucus will now be retained on the paper. Its properties are as follows:—when dried on paper it exhibits a bright surface; on being moistened, however, it rapidly assumes its original appearance. It is insoluble in sulphuric acid, but the nitric and acetic acids dissolve it in large proportion, and the solution is precipitable by ferrocyanuret of potassa: caustic potassa in solution dissolves it entirely.

Salivary mucus.—The saliva, as it passes from the mouth, contains, in all probability, two kinds of mucus; one derived from the mucous membrane lining the mouth, and the other from the internal membrane of the salivary ducts. When saliva is allowed to stand it very soon separates into two parts; one a supernatant liquor of a slightly milky hue, and the other a deposit of a white colour, which in this state does not exhibit the ordinary physical characteristics of mucus. On pouring off the liquor, however, and then agitating the deposit with water, it immediately assumes the glairy character; indeed, without the addition of water it will exhibit a mucoid tenacity if an attempt be made to raise it from the vessel in which it has collected. The liquor which has been poured off from this dense form of the principle still contains a portion of mucus in suspension, which may be obtained by dilution with water, and may probably be a less coherent form of mucus secreted by the lining membrane of the salivary ducts. These two forms of mucus have much the same chemical characters, being insoluble in water and coagulable, and rendered firmer, by the acetic, hydrochloric, and sulphuric acids. The liquors obtained by digesting these acids on mucus are not precipitable by the addition of alkalies, which shows that this form of the secretion does not contain any free subphosphate of lime. It is dissolved by caustic alkalies and precipitable by the acids when thus dissolved: the solution in alkalies, however, is not complete, a residue being always obtained, which is soluble in acid, but which cannot be precipitated from the acid solution by means of caustic alkali, and, therefore, is not an earthy salt. Notwithstanding this, however, we can always obtain evidence of the existence of phosphate of lime in considerable proportion by incinerating mucus; and Berzelius considers the tartar formed on the teeth to be derived from this source. This form of mucus is considered by Berzelius to approach very nearly to that obtained from the stomach and intestines: it differs greatly from nasal mucus, which is soluble in the sulphuric and nitric acids.

Intestinal mucus.—The mucus of the stomach and intestines can be best obtained by washing the mucous surfaces of those organs taken from an animal that has fasted some hours: it is occasionally observed adhering to excrement. This mucus, when dried, is no longer capable of assuming the tenacious character on being moistened with water, but, according to an observation of Berzelius, requires an alkaline solution for that purpose: it is coagulable by the acids. The acetic acid acts powerfully upon it, solidifying it completely. None of the acids dissolve it; the acetic acid seems, however, to have a partial action, since the liquor obtained by digesting it is precipitable by the addition of infusion of galls, but not always by the ferrocyanuret of potassa. The caustic alkalies dissolve this mucus, and the addition of acids precipitates it when thus brought into solution.

Mucus of the gall-bladder has been examined, and appears to resemble that last described; it is insoluble in the acids and precipitable by them from solution in alkalies.

From the descriptions which I have now given I think it will be allowed that, inasmuch as the mucus which is obtained by the chemical analysis of different secretions fails to show, when subjected to tests, those agreements in reaction which must be regarded as essential to prove identity, the question as to the existence of any substance to which the name of "mucus" should be applied, as one of the proximate elementary animal bodies, should be regarded as concluded. That there is always a matter present in the secretions of mucous membranes, which possesses a glutinous character, and to which the physical properties of the secretion are owing, is undoubtedly true; but this is quite a distinct question from whether or not this tenacious constituent be entitled to the rank of a proximate element: and the fact of a difference being observed in the chemical reactions of this body, as obtained from various secretions, strongly opposes such an idea. In order to examine into this question I made, some time ago, at the suggestion of Dr. Bright, some chemical observations on those effused fluids which partake more or less of the mucous character,* such as the effusions which occur in ovarian dropsy, and to compare the results obtained with similarly conducted experiments on other fluids of a more purely serous character, and also with serum of blood, as it appeared probable that some point of difference might be detected to which the mucoid character could be traced, notwithstanding the total absence of any substance obtainable in a solid form and exhibiting physical characters like those of mucus. I subjoin the examination of five fluids effused in ovarian tumours, and one of a purely serous character drawn from a case of ascites; the serum of blood is also offered for comparison; the separation of these fluids being carried only so far as the division into free albumen, aqueous extractive, and alcoholic extractive. These analyses were made on equal weights, or nearly so, of solid matters, obtained by evaporating each fluid, as previous observation had convinced me that the viscous character into the nature of which I was examining was quite independent of the degree of concentration of the effusions, the most tenacious generally possessing the lowest specific gravity.

	Ovarian effusions.					Fluid of	Serum of
	No. 1.	No. 2.	No. 3.	No 4.	No. 5.	Ascites.	Blood.
Albumen	4.50	4.57	3.75	6.17	1.15	6.02	8.77
Aqueous extractive	4.94	4.73	4.79	3.25	7.05	1.43	0.35
Alcoholic extractive	0.54	0.70	1.45	.57	1.79	2.11	0.87

These analyses at once showed that the aqueous extractive existed in greater proportion in the tenacious fluids of ovarian cysts than in the more serous effusion of ascites and the serum of blood; but another difficulty remained to be solved, which was, that some of these viscous liquors which were less mucoid in character than others, did not indicate the cause of such difference when the examination had been extended only to the separation into the three parts above mentioned, viz. albumen, aqueous extractive, and alcoholic extractive. On incinerating the aqueous extractive, however, so as to ascertain the proportion of animal matter and alkaline salts contained in it, I discovered that, while those specimens which showed the mucoid character in a more marked degree contained salts and animal matter in nearly equal proportions in their aqueous extractive, those in which the mucoid character did not greatly predominate either showed a deficiency or excess of salts; both conditions appearing more or less to interfere with the perfect development of the peculiar tenacious character of the secretion. I have now to notice the late ingenious and valuable observations of Dr. Babington, who has done more to assist this inquiry than any observer who has as yet examined into the subject. In a paper published in the fifth number of the Guy's Hospital Reports, Dr. Babington described some experiments showing that various albuminous matters were capable of assuming the mucous character by mixture with the alkalies. Serum of blood, pus, milk, and white of egg were all so affected; and the glairy mass so obtained was insoluble in water, precipitable by diacetate of lead, but not by bichloride of mercury or infusion of galls. It admitted of being washed with water till all traces of alkalinity were removed, but it still retained its mucous character. This synthetical formation of mucus is a most important fact; and I see no reason whatever to doubt that the artificially formed viscous mass differs from that secreted by membrane. It is true that the latter always contains microscopic globules, which of course are wanting in the artificial product; but these globules are, I believe, in no way connected with the viscous character of mucus, but are rather superadded to it, and frequently in very small proportion to the mass of the secretion.

The experiment of Hunter, who consolidated albumen by the addition of hydrochlorate of ammonia, as also the observations of Dr. Pearson on the action of some others of the neutral salts on pus, are confirmed by Dr. Babington in the paper to which I have alluded. The microscopic history of mucus, or rather of those organic globules which accompany the secretion, is a matter of considerable interest: before entering upon it, however, I wish to state my reasons why these globules are not, according to my belief, the cause of the viscous character of mucus. In the first place we do not observe them in sufficient numbers to authorize such an opinion; and, secondly, some of the most viscous forms of the secretion do not become corrugated to any perceptible

* See Guy's Hospital Reports, April 1833.

degree by the addition of concentrated saline solutions, whereas, by some experiments lately made with my friend Mr. Lane, I have been satisfied that the mucus globules are so affected, and may easily be observed, under a powerful microscope, to expand or contract according as water, or strong solutions are mixed with them. The mucus globule admits, in fact, of the exudation or imbibition of fluids according to the laws of endosmose and exosmose, and were the greater part of a mass of mucus composed of these globules, we should observe it to corrugate in concentrated solutions; but such is not the case, as I have before stated, with many of the most viscous forms of mucus, while the mucus of the bladder, on the contrary, which (except in severe diseases) is one of the least coherent forms, shows a tendency to contract under such circumstances, and on microscopic examination proves to contain globules in large number in proportion to its mass. This reaction, I think, renders it very probable that the view I have mentioned is the correct one. Most forms of mucus swell when moistened by water or weak solutions; but this is no proof of action on organic globules unless the opposite experiment (contraction by strong solutions) can be successfully performed. The mucus globule varies greatly, as seen in different secretions; so much so that any one who has examined this subject microscopically must be familiar with a form of globule peculiar to each secretion. I shall first describe the globule generally, and then proceed to notice its varieties in appearance. The mucus globule is nearly transparent, and larger than the blood globule. As it exists in the saliva and urine it is of a very regularly circular form, with a well defined margin and a somewhat granular surface. In the more adhesive forms of expectoration, however, it loses this well defined and rounded form, and its translucence is impaired; the granular surface can always, however, be seen. In a portion of mucus taken from the back of the throat I lately had an opportunity of examining this last mentioned condition, and took occasion to examine whether or not it depended on a partially empty condition of the globule, which could be remedied by the addition of water. I found, by careful treatment, in this way under the microscope, that the bodies gradually assumed a more rounded form, and eventually exhibited an appearance almost identical with the more transparent globules observed in the saliva and urine. By subsequently adding a concentrated solution of sugar to them, however, the original appearance was speedily reinduced, owing to the endosmodic action of the sirop. This experiment has led me to a belief that the cause of difference in the microscopic appearance of the mucus globule, as seen in different secretions, is attributable rather to the circumstances under which it is placed than to any difference in organization.

It would appear, from the facts collected up to the present moment on this subject, that we are justified in considering, 1st, that mucus is a compound of albumen in a state of close combination with alkaline salts, and probably free alkali; 2nd, that the artificial compound formed by the addition of alkalies and neutral salts to albuminous matter is essentially the same as mucus; 3rd, that the mucus globule is superadded to the viscous matter in the secretions of mucous membranes, and is in no way concerned in imparting the peculiar tenacious character to such fluids.

A great deal of trouble has been taken to devise chemical means of distinguishing between pus and mucus, or to detect the presence of the former when existing combined in small proportion with the latter. No chemical method of inquiry can ever be applicable to this question: the microscope must be had recourse to for the detection of the pus globule, if the mucus be suspected to contain it in quantity so small as to escape casual examination. When pus is present, however, even in very small proportion to the mucus, its physical characters are so distinct that no chemical or microscopical tests can possibly be required. Considered as a means of proof, the folly of using chemical tests is at once apparent when we recollect that the question as regards pus is entirely one of structure, and we cannot in reason use chemical tests to determine the presence or absence of a globule. When pus exists as a deposit in urine, we may easily distinguish it from the phosphates with which it is sometimes confounded by adding an alkali, as recommended by Dr. Babington, in which case the deposit (which must be previously separated by decantation from the urine) assumes the glairy character of mucus, and thus shows its albuminous nature. As affording us a distinctive test, therefore, between these two substances, chemistry becomes useful; but inasmuch as the addition of alkali to most forms of albuminous matter developes a mucous tenacity, the re-agent cannot correctly be called a test for pus. We become assured of the presence of pus by this reaction only, because previous experiment has shown that the phosphates and pus are the only two substances assuming a peculiar and similar appearance in the urine.

(G. Owen Rees.)

MUCOUS MEMBRANE.—This term has been usually and properly restricted to those large expansions of membrane, in the interior of the body, which are continuous with the external tegument: but it is impossible, in the present state of knowledge, to treat of these apart from the true glands and the skin, which form with them a great system, to which the generic term *mucous* will be applied in this article.

Many anatomists since the time of Bonn* have treated of the mucous membranes and skin under the common title of tegumentary membranes; and the opinion has been gradu-

* Bonn, Specimen Anatomico-Medicum Inaug. &c. de continuationibus membranarum, &c. in Sandiforti Thesauro, tom. ii. p. 265. Roterod. 1769.

ally gaining ground, that all the glands furnished with excretory ducts have a very close relation to the former, in which their ducts for the most part open. Still, it does not appear that the proofs of this alliance have been hitherto, by any author, deemed sufficient to induce him to blend these several parts under a description common to them all. Even Müller, in whose philosophical work on the glands is contained so much new and important evidence of this relation, continues thus to sever them in the late edition of his Physiology. But, indeed, although much weight is to be granted to the arguments drawn from continuity and occasional convertibility of structure, course of developement, rough analogies of composition or of function, and sympathies under disease, it must be allowed that hitherto that most important of all proofs has been all but wanting, which, as I shall endeavour to show, is capable of being derived from minute anatomical analysis.

The researches which I have hitherto been able to make on this subject are still so incomplete, that I should have gladly delayed their publication for some time longer, had the progress of this work admitted of it. As it is, I shall state the conclusions to which I have been led, and the grounds they rest upon, (pointing out, as far as possible, where farther examination is demanded,) with the hope of thereby giving a clearer and more satisfactory view of the structure and relations of this important class of tissues than could be otherwise accomplished.

I shall point out that the skin, mucous membranes, and secreting glands, consist of certain elements, which the anatomist may detect and discriminate, some of which are essential to their tissue, others appended or superadded,—and that the broad characteristic distinctions between these structures, appreciable to ordinary sense, as well as the innumerable gradations by which they every where blend insensibly with one another, are solely due to various degrees and kinds of modifications wrought in the form, quantity, and properties of these respective elementary parts.

The skin is the outer tegument of the body; the mucous membranes form its internal investment, and are continuous with the skin. The ducts of all glands are continuous either with skin or mucous membrane, and their true secreting portion, as already described, (see Gland,) is merely a further prolongation of the same tissue. These offsets, like the great mucous tracts, are in the direction of the interior of the body; they form follicles and tubes of infinite variety, and, however complicated, may still be regarded, in a certain sense, as external to all other textures. Thus the mucous system may be described as a great and uninterrupted membrane, every where perfectly closed, in which the rest of the animal, or the *parenchyma*, is enclosed. This membrane has two surfaces, the one free, superficial or external, the other attached, deep, or parenchymal. It is on the parenchymal surface that the appended structures (viz. blood- and lymphatic vessels, nerves, and areolar tissue) are found in more or less profusion.

The functions of the mucous system, numerous and diversified as they are, all bear a distinct reference to its really external anatomical position, and by this circumstance they are associated together: the principal are sensation, absorption, secretion, excretion, and defence of the parts lined by it against the contact of foreign bodies.

A glance at the opinions that have prevailed concerning the structure and relations of the mucous membranes, will exemplify, more clearly perhaps than any other course, how imperfect have been the means employed, until a very recent period, in researches into minute or structural anatomy. The distribution of their bloodvessels had indeed been studied with brilliant success by Ruysch, Lieberkühn, and others, by the aid of injections, the admirable delicacy of which no modern art has surpassed; and somewhat of their extensive connexions, general properties, and even of their texture, had been divined from rough dissection, maceration, and observations on the mode of their developement and on their morbid states. But the ignorance that really prevailed, as to their intimate structure, is abundantly evinced by the number of disputed questions, the absence of precision of detail, and the substitution of loose and unwarranted analogies in its stead. Within the last five years discoveries have been made which throw a new and most important light on the whole subject, and when viewed in connection with one another, must be considered to have greatly simplified our knowledge respecting it. These discoveries, due chiefly to Boehm, Boyd, and Henle, result from examinations of recent specimens with the microscope, and those of the last observer, which are especially valuable, were made with high powers employed upon a single tissue (the epithelium) in different forms and situations. It is this kind of research that promises the most enlarged and trustworthy results to any one who will follow it in a spirit of due caution against hasty generalization, and which has already done so much in the present day towards a complete remodelling of our ideas, both concerning the elements of organization and their union to form compound tissues.

Before proceeding to a description of the anatomical elements of the mucous system, it is necessary to premise that a great portion of the membranes, usually termed mucous, are glands of a complicated structure, arranged in a membranous form, consisting of a closely packed mass of secreting tubules, which open on the general surface, and are essentially involutions of it. The bloodvessels and other appended tissues occupy the intervals of these tubules, and so approach the surface; but, nevertheless, they always remain on the deep or parenchymal aspect of the mucous tissue. So, the same membranes present projections, which are nothing more than hollow evolutions of the same mucous tissue, into which the appended tissues are extended. The same remarks apply strictly to many regions of the skin. Hence it becomes necessary to guard against confounding such *compound membranes* with the *simple mucous tissue*, of which these and all other portions of the mucous system consist.

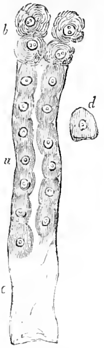
Of the ultimate structure of the mucous system.—It has been already stated that the mucous tissue is essentially an uninterrupted membrane in which the other tissues of the animal are contained. A very cursory attempt will serve to shew how much more easily it admits of being separated and examined in certain situations rather than in others. This variety depends chiefly on the difference of its arrangement and connexions in different regions. In the testis and kidney, the capillary vascular rete, spread over its parenchymal surface, has no intimate attachment to it, and the appended areolar tissue is in very small quantity. In the testis especially, this latter may be said to be almost wanting as an investment to the individual tubules, being, as it were, disposed as a collective covering to the entire organ, sending partial septa into its interior, and bearing the name of Tunica Albuginea. In the kidney, a more intricate vascular rete in a great measure supplies the place of areolar tissue. Hence, in these viscera, the simple mucous element allows of being isolated with remarkable facility. In the liver, its isolation is almost impracticable, owing to its lying in the interstices of a capillary plexus that may be termed *solid*, from its being extended uniformly in every direction. The intricacy of the interlacement of the mucous and vascular elements in this organ is sufficient to explain the total ignorance that prevails concerning the mode of termination of the biliary ducts, and concerning their size, shape, and connexions in the lobules of the gland. In many other true glands, the mucous tissue may be submitted to examination without much difficulty; examples of which may be seen in the pancreas and salivary glands, with those allied to them, such as the duodenal glands of Brunner, the buccal, palatal, arytenoid, tracheal, &c.; and in the sudorific glands of the skin. In the compound membranes also, as that of the alimentary canal below the cardia, and the more highly developed parts of the skin, the mucous element may be generally distinguished from the tissues in connexion with it in a satisfactory manner. But in the plane expansions of the simple membrane which line the bony cavities of the nose and ear, its isolation and the demonstration of its structure are far more difficult, for reasons which will be afterwards explained, and our knowledge of it here still rests partially on the ground of analogy.

In the mucous tissue there are two structures that require to be separately described, viz. the *basement membrane* and the *epithelium*. The basement membrane is a simple homogeneous expansion, transparent, colourless, and of extreme tenuity, situated on its parenchymal surface, and giving it shape and strength. This serves as a foundation on which the epithelium rests. The epithelium is a pavement composed of nucleated particles adhering together, and of various size, form, and number. The following general observations on these elementary parts will receive illustration as we advance. Neither the one nor the other is peculiar to the mucous tissue in the sense either of being invariably present in it, or of not being found elsewhere. There are certain situations of the mucous system where no basement membrane can be detected, and others from which the epithelium is absent. Both, however, are never absent together. Again, a structure apparently identical with the basement membrane is met with in numerous textures besides the mucous, and all internal cavities, whether serous, synovial, or vascular, or of anomalous kind, (as those of the thymus, and thyroid body) are lined by an epithelium.

In the ensuing description these circumstances will be enlarged upon, and the exceptions and local peculiarities pointed out, as far as I have been able to ascertain them. At present, I would say that these two elements are *generally* present. The most interesting questions in animal physiology are involved in the determination of the nature and offices of these two elementary parts of the mucous tissue. The discovery of them is, however, too recent, and our knowledge of their history as yet too incomplete, to allow of any certain conclusions on the subject. Both present various modifications in different situations, the study of which is of great importance with reference to their function. It will now be our business to descend to a particular account of each.

Of the basement membrane.—The basement membrane of the mucous tissue, as displayed in the kidney, is an extremely thin, transparent, and homogeneous lamina, simple and entire, without any aperture or appearance of structure (*fig.* 273, *c*). It forms the parenchymal wall of the uriniferous tubules; gives them their size, shape, and stability; is in relation, on the one hand, with the vascular system of the organ, and on the other with the epithelial lining. It is simply in contact with the capillary plexus, which is fixed chiefly by their mutual interlacement; but the epithelium adheres to it by an organic union. When detached from the vascular rete which it traverses, and deprived of its epithelium, it readily wrinkles (*fig.* 273, *c*); and such is its tenuity, that it is sometimes only by the folds thus occasioned that it becomes visible at all. The epithelium readily separates from it after a slight maceration, and also in many diseased states of the organ, such as inflammation and Bright's disease. Though this basement tissue is so delicate, its presence or absence in any fragment of a separate tubule may always be ascertained by the aspect of the marginal outline; if this be linear and well defined, the basement membrane is present, but if irregular and broken, the epithelium only (*fig.* 273, *a*, *b*). It sometimes happens that when the epithelium may seem to be altogether detached, the basement membrane retains, scattered evenly over its surface and at some distance apart, a number of roundish marks, of the size and aspect of the nuclei of epithelium particles. These are

Fig. 273.



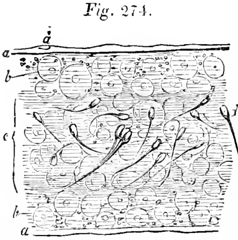
A portion of a tubule of the human kidney, magnified 300 diameters.

At *a*, the basement membrane and epithelium are both seen in a natural state. At *b*, the basement membrane has been separated, and the epithelium is somewhat swollen, and its outline 'woolly.' At *c*, the epithelium has been detached and the basement membrane is seen somewhat wrinkled: *d*, a detached epithelial particle seen in face; its minutely mottled texture is not represented in the wood-cut.

most probably the early condition of the new or advancing series of these particles. Its thickness in the kidney certainly does not exceed the $\frac{1}{20000}$th of an English inch. I have discovered, that in the Malpighian bodies of the kidney, which are the dilated extremities of the uriniferous ducts, with an enclosed tuft of arterial capillaries, the basement membrane is often, to some extent, naturally bare, i.e. without a covering of epithelium. This is the only situation of the body in which such an arrangement is known.

In the testis, the same membrane may be shewn without difficulty to be that which gives to its secreting tubules their peculiar strength; and here, as might be expected, it is somewhat modified. The difference is principally as regards its thickness, which here reaches $\frac{1}{10000}$th of an English inch, and in some animals

Fig. 274.

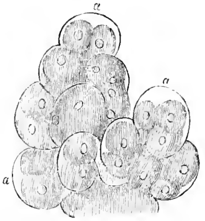


A portion of a tubule of the testis (Guinea-pig, Cobaya), magnified 300 diameters.

a a, basement membrane; *a'*, corpuscle in its substance; *b b*, epithelium in situ, consisting of particles of different dimensions, with minute granules in their interstices; *c*, cavity of the tubule full of detached epithelium particles, of various size and appearance, and mingled with numerous seminal animalcules; *d*, one of these seminal animalcules.

even exceeds that amount, its essential characters, however, remaining the same. In the larger tubes, emerging from the gland, this tunic becomes gradually invested by a delicate fibrous layer, by which the vascular network is attached to it, and which at first sight may appear to form an integrant part of the wall of the canal.

Fig. 275.



Terminal vesicles of the pancreas of the dog, magnified 300 diameters.

The basement membrane is seen at *a a a*, where the epithelium has been a little detached.

In the salivary and all the allied glands, the basement membrane admits of being easily demonstrated. A very thin slice of the fresh organ should be torn by needles, gently washed, and inspected under a high power. The terminal vesicles of the duct will then be brought into view and their outline seen to be perfectly sharp and linear (*fig.* 275, *a a a*). In parts where the epithelium which they contain has been loosened, the basement membrane will be left in relief. It is of extreme delicacy; and, as in all other situations, its capillary plexus (when well filled with coloured material) may be seen ramifying, not in its substance (for its tenuity renders such a disposition impossible), but on its parenchymal surface.

I have sought in vain for the basement membrane in the lobules of the liver, and I am inclined to think that it does not exist in this gland, except in the excretory part of the bile ducts.

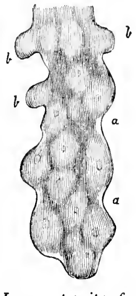
In the air-cells of the lungs the basement membrane assumes a most interesting and remarkable developement, for it constitutes almost the entire thickness of their walls, the epithelium being of extreme delicacy. It appears to be here strengthened by interlacing arches of elastic fibrous tissue, but to be itself transparent and homogeneous, as elsewhere. It is on its parenchymal surface that the close vascular web is spread out. (See PULMO.)

But this membrane may be also detected in every part of the alimentary tube, which is more characteristically mucous, in that, viz. intervening between the cardia and the lower extremity of the canal. Here it deserves an attentive study on account of the apparent complexity of its foldings, and because its existence here offers the most unequivocal proof which we possess, of the anatomical identity of the true glands with the membranes usually called mucous. As it is more delicate in this part than any other, and difficult of detection by reason of the enormous preponderance of its epithelial investment, I shall describe the manner in which it may be best observed. The specimen should be as fresh and healthy as possible, or should have been immersed in alcohol immediately on its removal from the body; a fragment of the tubes of Lieberkühn should then be scraped off, pulled to pieces, and examined in a fluid medium under a high power. The margins and rounded extremities of the tubes will then be seen to be sharply defined, as in the cases already mentioned, and to be formed by a structure independent of the epithelium, which latter forms $\frac{19}{20}$ths of their thickness. This structure is the basement membrane. When masses of epithelium, escaped from the tubes and bearing their form, are met with floating around, their outline is uniformly irregular, and, as it were, woolly. Sometimes, as in the kidney (*fig.* 273), the basement membrane is seen up to a certain point only, beyond which it has been detached; and in less recent specimens a tube of basement membrane is sometimes seen, containing a mass of broken-down epithelium.

If the part selected for examination be the stomach, the same precautions should be observed, for here this membrane is, if possible, more delicate than below the pylorus, and the epithelial particles are often so large as to bulge the tubes very irregularly, especially towards their blind extremities. It is between these bulges that the basement membrane may be best seen (*fig.* 276).

Nothing is more difficult than to explore, in a satisfactory manner, the internal structure of the intestinal villi. Their thick epithelial caps and their abundant vascular rete are readily demonstrable, but the arrangement of the lacteals, which undoubtedly exist in them, and of the structure on which the epithelium immediately rests, has hitherto almost entirely eluded our research. In vertical sections of the recent small intestine of the Carnivora, I have several times seen the direct continuity of the epithelium covering the villi, with that lining the tubes which open at their base; and also a distinct continuity between the interior of the villi, where the vessels are spread out, with the vascular intervals between the tubes, which contain the fine capillary web surrounding the tubes, and likewise give passage to the branches to and from the villi. It is then difficult to avoid the belief that the basement membrane of the tubes is continued under the epithelium of the villi, to support it, and form a part of those remarkable projections. Nevertheless I have not been able to see it in an isolated and distinct form, and do not therefore assert its positive existence; only I believe that the fact that the injected vessels of a villus, when seen in profile at its margin under a high power, and when the epithelium has been removed, seldom come to the extreme edge, is attributable to the circumstance of the basement membrane still investing them. This membrane, if it really exist here, adheres intimately to the parts within the villus.

Fig. 276.



Lower extremity of a stomach tubule from the dog (*Canis familiaris*), *magnified* 300 *diameters.*

At *a a*, the basement membrane is seen between *b b b*, bulging epithelial particles.

It might seem at first sight a hopeless task to search in so dense and complicated a structure as the skin, for the analogue of a membrane like that I have been describing, which, in no situation where it can be unequivocally brought into view, exceeds the 8000th of an inch in thickness. But as it must exist, if at all, between the epidermis and the vessels and nerves of the cutis, in a position sufficiently determinate, much of the apparent difficulty is removed. The most favourable situations for its detection are those in which the skin is highly developed, presenting, like the small intestine, villi (termed papillæ) on its free surface. The close resemblance between these papillæ and the villi of mucous membranes has been observed by many anatomists. The distribution of the vessels within both is essentially the same. Here, then, under the epidermic layer, we might expect to find the basement membrane. I have removed with great care the whole of the epidermis from a thin vertical section of such a specimen (and it is better to have previously steeped it in solution of carbonate of potass), and have then examined the outline of the bare papillæ with a power of 300 diameters. This outline is sharply defined, and appears to be formed by a homogeneous membrane, enclosing the vascular and nervous contents. This membrane I believe to be that which I am now describing, though, as in the case of the intestinal villi, I have never been able to isolate it, and thus unequivocally prove its presence. This is a part of the skin which has never been noticed by anatomists on account of its tenuity,

Fig. 277.

but which is quite distinct from the cuticle, and the great mass of that complicated structure to which the terms 'cutis' and 'dermis' are applied.

A very strong reason for believing this membrane to be present in the skin, is the fact of its existence in those minute organs, so profusely scattered under the cutaneous surface, the sebaceous and sudoriferous glands. In *fig.* 277 I have represented it in a portion of one of the latter, taken from the axilla, where they are very large. These glands are nothing more than involutions of the external tegument, and correspond closely with the labial and allied glands connected with the ordinary mucous membranes. It is impossible to suppose that a structure attaining so marked a developement in those parts, should be wanting in the general superficies, with which they are, at numberless points, directly continuous.

In other situations, where a simple expanse of mucous membrane is spread out upon a surface of the body, as in the œsophagus, pharynx, mouth, nose and its sinuses, vagina, bladder, &c. (from all of which, however, there are numerous prolongations called follicles and glands, which shew this structure well,) a basement tissue such as that described has not been shown to exist. Its existence rests at present principally on analogy, and it is difficult to say whether it be not more or less modified. Certain of the peculiarities presented by these several parts depend on a modified form and greatly augmented mass of the epithelial element, but many also on varieties in the areolar and vascular tissues underlying the mucous tissue, and, properly speaking, forming no part of it. These will be treated of under the topographical description of the membrane.

Of the epithelium.—A very brief period has elapsed since it was universally held that most mucous membranes wanted epithelium, and their analogy with the skin was only maintained in this particular by a fancied resemblance drawn between epidermis and mucus. One of the principal results of microscopic observation, conducted with the improved modern instruments, is that of Henle, proving not only that this structure is present throughout the mucous system, but that in most situations it is so abundant as to constitute nearly the whole material of the tissue. This fact, as yet so novel, coupled with the discovery announced at the same time of the occurrence of a lining of analogous character on all internal cavities, makes the study of this structure under its varied forms peculiarly interesting and important. It will readily be conceived how wide a field is here opened to view, and how premature it would yet be to attempt to offer a general history of such a structure. The numerous questions presenting themselves on every side render this impossible; and if it were not so, the scope of the present article would oblige me to confine the description to those forms of epithelium met with in the mucous system. In acknowledging the great obligations I am under to Henle's admirable paper on this subject, I may state that the following account has been written as much as possible from my own observations.

By the term epithelium is now meant a layer of particles or modified cells, furnished with nuclei and nucleoli, lining an internal surface of an organized body, and by their apposition and union constituting a kind of pavement. A similar investment to an external surface is styled epidermis. Both these, in their ordinary forms, will be embraced by the following description.

Epithelium is an organized structure endowed with vitality. This is shewn by its form, the process of its growth, and the living properties it displays. Of these the most eminent is that of ciliary motion, which in all the higher animals is performed by cilia clothing the free surface of epithelial particles. But in very many situations, if not in all, the processes of nutrition carried on in the epithelial layer of the mucous system differ materially from those of other organic tissues; the old elements, which in other cases are reconveyed into the blood, being here shed on the free surface of the membrane, and thus becoming at once eliminated from the system.

The epithelial particles preserve a greater resemblance to the form of the development cell than most other tissues. In many parts they continue to be truly cells throughout their existence, and in no instance is the nucleus, from which they have proceeded, absorbed.

In connection with a wide and varied range of function, these particles present numerous modifications of form, bulk, and texture, the leading features of which have been pourtrayed by Henle. The following arrangement, however, differs in several respects from that proposed by him,* and is more in accordance with what I have myself observed. Founding it on the anatomical condition of the particles and on their office, I distinguish three varieties,—the *lamelliform or scaly*, the *prismatic*, and the *spheroidal*. These all run together by imperceptible gradations. The particles may be also divided into *non-ciliated* and *ciliated*, the scaly being always bald, the prismatic and spheroidal in some situations furnished with cilia.

Of the lamelliform or scaly variety.—This consists of broad flattened particles (or scales, properly so called), having an angular outline (caused by their lateral apposition) and a nucleus, which is generally eccentric. These scales form layers of extremely variable thickness. They are generally, however, superimposed in great numbers over one another, as in the mouth, fauces, and œsophagus of the human subject, where they constitute the opaque defensive investment so visible to the eye in those parts.

But the best-known example of this form is presented by the cuticle, which from its exposed position is thicker and denser than any internal epithelium. This variety, then, is the one which offers the most convincing proof of

* He divides it into pavement epithelium (or the scaly), cylinder epithelium (or the prismatic), and ciliated epithelium. See Müller's Archiv. 1838.

the homology of the mucous membranes with the skin. The term 'scales' is only applicable to these particles in the last of the stages through which they pass. They first appear on the surface of the basement membrane as granular dots, each of which soon becomes invested with a cell membrane. Both nucleus and cell increase in size up to a certain point, the cell being then more or less globular, and containing a material that appears transparent and almost entirely fluid. By this circumstance, chiefly, it is distinguished from the spheroidal form of particle, presently to be noticed. The cell now begins to flatten, loses its fluid contents, and is at the same time the seat of certain changes by which its chemical properties are modified. At length its opposite surfaces unite, except where the nucleus intervenes, and a lamella of extreme tenuity results, which being now arrived at the surface is loosened and shed. It appears to be by the continual pressure arising from the growth of newly-formed particles that the peculiar characters of this variety result. Accordingly, the scales are only found constituting the superficial layers of a series (*fig.* 278, *a a′*). It is met with in those parts only where foreign pressure, or more properly friction, has to be encountered. In such parts a thick coating of epithelium is evidently desirable, and the hard and almost horny qualities which these particles at length assume where most exposed to violence, admirably adapt them for their object. On such parts, moreover, cilia would not be needed, and it would even seem that this variety of epithelium when converted into true scales possesses neither sufficient substance nor vital power to develope and support these exquisite organs.

The scaly epithelium is remarkable for the tenacity with which its particles adhere to one another, and to the surface on which they rest. This adhesion is manifest at all the stages through which the particles pass. It is stronger between particles at the same stage than between those at different stages of growth, so that there is always a tendency to a separation into successive laminæ on maceration or otherwise. Hence have resulted the divisions of the epidermis into two, three, or more layers, and especially that remarkable fallacy of regarding the *rete mucosum* as a distinct structure. How far this adhesion is owing to the presence of an intercellular substance in all instances it is difficult to decide; but it seems highly probable that, in the deepest layers, where the particles are small and rounded, such a substance must exist in considerable abundance, filling up the interstices, and serving as a kind of *blastema*, in which the nuclei (or cytoblasts) of fresh particles originate. I have lately (Jan. 1842) ascertained a very curious fact, giving evidence of this adhesion. This is, that the delicate threads drawn out of the cutis when the cuticle is stripped from a piece of macerated skin, consist entirely of the epithelium of the sweat-ducts, the particles of which are so intimately united with one another, and with those of the deeper layers of the epidermis, as to allow of being thus dragged out of their tube of basement membrane, often for a length of an eighth of an inch.

The scaly epithelium is subdivisible into two forms, the *regular* and the *irregular*. In the *former*, the scales are united edge to edge in a regular manner, as in the skin of the Frog and other reptiles, and on many internal surfaces, especially in the lower animals. In this form, the particles do not become so thin as in the other, and the superficial scales are cast off in laminæ consisting of a single series and of uniform thickness. In the *latter* form, they overlap one another without order, and present no regular figure. This is the ordinary form, and is that presented in the skin and other parts of Mammalia and Birds.

*Of the prismatic variety.**—In this the particles have the shape of small rods, disposed endwise on the basement membrane, in a single layer, the thickness of which depends on their length. These rods are united to one another by their sides, which are flattened for that purpose. They are, therefore, prisms and not cylinders, as Henle terms them. They are also almost invariably of very unequal thickness in different parts, being bulged somewhere near the middle by their nucleus, which is oval, with its long axis parallel to that of the particle. Their deep or attached extremity, also, usually tapers to a point, in order, probably, to allow room for new particles to spring up in the intervals. This is more decidedly the case where they clothe a convex surface, (as that of the

* To this the very appropriate term *columnar* has been lately given by Professor Todd.

intestinal villi,) and their sides tend to assume the direction of radii from a common centre. Hence they are sometimes even triangular in outline. Their opposite or free extremity is much thicker, often as thick as the part bulged by the nucleus, and near this extremity neighbouring particles are generally very intimately attached to one another, having often the appearance of being blended into a single mass. The best example of this is on the villi of the small intestine (*fig.* 280). The contiguous particles, however, are fitted closely together in the greater portion of their length, and to effect this the bulging nuclei vary in the height at which they are placed. There can be no doubt, that, in certain situations at least, as will be afterwards shown, these particles are being continually shed, and consequently are being perpetually renovated. But it is very difficult to ascertain their early condition and changes, and I am not aware of any satisfactory observations having been made for this end. From the great facility with which they become detached from the surface they invest, it is next to impossible to examine them in situ on thin verti-

a, small particle, apparently in an early stage of development. The nucleus is smaller than in the other specimens; *b*, another more advanced—the nucleus and surrounding substance are both larger, especially the latter, which presents a fine granular texture; *c*, a particle made angular by pressure against others. It presents two nuclei, as though formed by fission; *d*, another of a different shape; *e*, detached nucleus, showing its transparency and clear outline; also two excentric dots, the nucleoli. *Magnified* 300 *diameters*.

cal sections. But there is no reason for supposing their mode of growth to be originally different from that of the scaly variety. Their nuclei probably appear first on the surface of the basement membrane, and around these a cell is developed (*fig.* 280, *a*). But this cell from its earliest period seems to contain an amorphous substance, which under high microscopic powers looks finely mottled, but not so definitely so as to allow of being called granular. As the particle advances towards its full size, it loses its cell-membrane, and when complete is to be regarded rather as a solid mass of organic substance, surrounding a nucleus, than as a cell. Here, then, is a striking difference between the *scale* and the *prism*: maturity being marked in the one by the disappearance of the substance of the cell; in the other, by that of the cell-membrane.

Of the spheroidal variety (see *figs*. 273 to 277).—In this the particles are of a rounded

form, though generally somewhat flattened where they touch. They are always thick, from the substance they contain. It is this variety that constitutes the chief mass of the secreting glands, and hence it might not improperly be styled *glandular*. It corresponds with the prismatic variety, in its usually constituting in the glands a single layer, and in the predominance, from the first, of its substance over its membrane. In the glands, indeed, the membrane can seldom be discerned at all, and the substance surrounding the nucleus, though more bulky, has the same finely mottled character already noticed in the prisms. In other situations the cell-membrane is persistent, but even then it never flattens into a scale. This variety presents in the different glands numerous modifications, which have not yet been studied with the accuracy they merit. It is difficult to reject the belief that it is intimately concerned in the glandular function, and varies in correspondence with it.

To the preceding summary account of these three principal kinds of epithelium much might be added respecting the intermediate forms. This, however, does not appear to be required in so general a description. The spheroidal and the prismatic are seen blended in the specimen I have figured from the human membrana tympani (*fig.* 281).

Of the non-ciliated and ciliated epithelium.— The true scaly variety appears never to be clothed with cilia. The prismatic epithelium is that which most commonly bears these vibratile organs. They are placed on the free extremities of the prisms in the respiratory tract and in the uterus and Fallopian tubes. The true glandular epithelium is always without cilia. This is a general fact, and one of great importance. But those varieties which seem intermediate between the spheroidal and the other two forms are often furnished with cilia; of which examples may be seen in the Malpighian bodies of the kidney, in the mucous membrane of the frog's mouth, and in that of the human tympanum (*fig.* 281). In all cases the cilia, when

They appear to present three stages or periods, showing a subdivision of the nucleus and a formation of two cells out of one; *d,* three fully developed particles, with cilia on their free surface; *e, f, g,* other complete particles, showing cilia on that part only which has formed a portion of the general surface of the membrane.
Magnified 400 *diameters.*

they exist, are developed only on that aspect of the particles which forms a portion of the general surface of the membrane.

It is as yet entirely unknown by what process the cilia are produced and nourished; whether the particles, with their cilia, are shed from time to time, and are succeeded by others, (as is most probable,) or whether the same organs remain, and merely change their component elements. (On the subject of CILIA in general the reader is referred to Dr. Sharpey's excellent article.)

Of the elementary tissues appended to the mucous system.—The two elementary tissues now described may be considered as the more essential constituents of the mucous system, or as forming the *simple mucous membrane.* This simple mucous membrane envelopes the rest of the body. It contains within its own substance neither vessels nor nerves, but is, strictly speaking, extra-vascular. By modifications, chiefly of the epithelial element, it is in itself capable of presenting great variety of appearance and properties in different situations. But in immediate connection with its deep surface, that is, with the basement membrane, there are certain tissues common to almost every part of the frame, but here assuming a peculiar arrangement and office, and by their diversities in various localities, occasioning the most complicated varieties of outward form, of structure, and of function.

These appended tissues are minute bloodvessels, a lymphatic network, nerves, and areolar tissue.

It has been already stated that in many parts the simple mucous membrane, by its innumerable minute involutions over an extensive surface, is formed into a *compound membrane.* Into the composition of this (of which a good example is afforded by that of the stomach) the appended tissues enter more or less largely, but they are likewise, in addition, generally spread out in great abundance as a layer underneath the compound membrane. This layer has been commonly termed *submucous cellular membrane,* (sometimes *tunica nervea,*) in the case of internal surfaces, and *cutis vera* or *dermis* in the case of the skin.

Bloodvessels. — These may be said to be universally present under the *simple* mucous membrane, with the exception perhaps of the cornea, where vessels, in the normal state, have not yet been demonstrated. The capillaries, in their simplest form, appear to be arranged as a plane network, such as that of the rectum of the frog (*fig.* 285). The interstices of this network vary much in size and shape in different localities. The most copious supply of blood distributed to any such membrane is that afforded to the air-cells of the lungs in all animals. Here this plane capillary plexus has areolæ scarcely exceeding the diameter of the vessels themselves. Where the membrane they supply is folded, however irregularly, they follow its surface, and hence result many varieties in their arrangement and inosculations. It even seems to be for the purpose of gaining a great freedom of inosculation between the capillaries that the extraordinary complexity has been given to many parts of the simple membrane, especially in the secreting glands. For many foldings from somewhat distant parts of the membrane are there brought into immediate proximity to one another, and are supplied by the same or closely connected vessels. This is remarkably exemplified in the testis, kidney, and liver. The capillary system of all these, as well as of other solid glands, may be styled a *solid plexus,* being extended in every direction, and presenting areolæ of nearly equal size in whatever plane a section of it be made. The liver presents the most perfect instance of such a solid plexus, and in it the vessels are of

Fig. 285.

Capillaries on the rectum of the Frog.
a, a, arteries; *b, b,* veins.

unusual dimensions, apparently to allow of the more free transit of the blood, which is here propelled feebly by the *vis à tergo* acting through the capillaries that form the portal vein. Though it has not been so described, I believe, from injections that I have made, that the whole organ is one such plexus, and that if it were possible to abstract from it all vessels larger than capillaries, and to leave these entire, all the lobules would still be connected together by capillary channels identical with those of which they themselves principally consist. Hence the lobules of the liver are not definitely bounded on all sides by a capsule of any kind, but here and there blend by continuity of substance with those adjoining them. The larger portion of their contour is, however, well defined by the ultimate twigs of the portal vein, and of the ducts derived from the lobule, as so clearly proved by Mr. Kiernan in his well-known paper.

The size of the capillaries varies much in different parts of the mucous system. In the liver they are very capacious, always one-third wider than the diameter of the blood globule, and sometimes nearly double. In the lungs they are almost equally great. In the intestinal villi also they are of large dimensions. In these organs they form a network on the inner surface of the basement membrane, and are supplied by an artery that ascends in the axis of the villus. The veins from this network are generally two, one on each side. This plexus of the villi is strikingly contrasted by that clothing the tubes that open at their base. In this latter I have observed the diameter to be as small as that of the capillaries of the salivary glands, which do not exceed the width of a blood globule. This disparity is another confirmation of the opinion that the villi are chiefly absorbing, and the tubes secreting organs. Many other varieties might be enumerated, but these are among the most remarkable.

Under most of the *compound* mucous membranes bloodvessels are spread out in great profusion, and especially in certain localities. The arteries and veins respectively form plane plexuses, more or less close, more or less intricate, from which emerge branches that pass between the foldings of the simple membrane and communicate with its capillaries, already described. There may even be a series of these arterial and venous plexuses situated one over another, and successively springing out of one another. The effect of this arrangement of an arterial network on one side of the capillaries and a venous network on the other side, is that the blood, besides being delayed in their neighbourhood, is most freely and equably distributed in the capillaries themselves: a condition which could scarcely be otherwise accomplished, since, in the case of a villous membrane at least, the capillaries form a series of isolated systems, of which one belongs to each villus. The arrangement now spoken of exists in the submucous areolar tissue of the stomach and intestinal canal, and in most parts of the skin. In the solid glands, where the capillaries form one continuous system, such arterial and venous networks are not found. At least such inosculations, when they exist, are few and rare. In the stomach of many fishes there is a plexus of great thickness under the mucous membrane. In the nose also, chiefly on the spongy bones and septum, there is a plexus of very large veins, well known to anatomists, and also a less capacious arterial plexus; smaller ones are met with in other parts, as the cheeks and lips, the palate and pharynx. The use of these, especially that of the nose, may be to serve as a diverticulum for the blood in cerebral congestions. These are the vessels that give way in ordinary epistaxis.

Of the lacteal and lymphatic vessels.—The lacteals have their sole origin from a plexus underlying the simple mucous membrane of the alimentary canal, and it is probable that in every part of the skin a close network exists, such as has been described by several anatomists (see LYMPHATIC SYSTEM). Considering the means hitherto at command for ascertaining the precise position of this network, it is not wonderful that disputes should have arisen as to whether it lies in the rete Malpighii, or within the surface of the dermis. I would hazard the opinion that the real situation of this plexus is underneath the basement membrane which is everywhere present in the skin.

Of the nerves.—These are numerous and varied, as might be expected from the position of the mucous system in regard to the rest of the body. They may all be styled *afferent*, and are divisible into three kinds, viz. the sensory, the excito-motory, and the sympathetic. The nerves of special sense distributed to this system are those of smell, taste, and touch. The nerves of common sensation and the excito-motory nerves are almost exclusively found here. The tubules of the sympathetic nerves are chiefly given to the proper mucous membranes and to the glands. All these will be considered more at length under other heads, and they are therefore only referred to here.

Of the areolar tissue.—Before describing the remarkable varieties presented by this tissue under different parts of the mucous system, I must advert to its constitution in those situations where its ordinary characters are well marked—as in subcutaneous fascia, in muscle, on the exterior of the pharynx, &c. Singular as it may appear, there is no correct account of this structure in any of the works on minute anatomy. It in truth consists of two tissues, distinct from each other, and respectively allied to the white and to the yellow fibrous tissues. The *white fibrous element of areolar tissue* is chiefly in the form of bands of very unequal thickness, in which are to be seen numerous streaks taking the general direction of the whole, but not parallel to the border, nor continuous from end to end. These streaks more resemble the creases of a longitudinal folding than intervals between separate fibrillæ, for which they have been mistaken. These bands split up without difficulty in the long direction, whence result fibrils of the most varied width, the finest being far too minute for measurement, even with the best instruments.* These bands interlace and cross one another in various directions, and their natural course is wavy. They frequently subdivide and join those near them. Besides these bands, commonly called fasciculi, there are some finer filaments of the utmost tenuity which seem to take an uncertain course among the rest. The *yellow fibrous element* is everywhere in the form of solitary fibrillæ, which correspond in their essential characters with the tissue of that name. They are disposed to curl, and are truly branched at intervals of variable length; these branches (which usually retain the size of the fibril from which they spring) becoming continuous with others in the neighbourhood. They have higher refractive properties than the white element, and their borders are consequently darker.

It is easy to overlook this twofold composition of areolar tissue in specimens examined in water, but their discrimination is made easy by a trifling artifice. This consists in adding a drop of acetic acid, which instantly swells the white bands, and makes them transparent, but produces no change in the yellow fibrils. These effects of the acid may be watched, if the agent be made to spread gradually over the specimen; and there can scarcely be conceived a more beautiful example of the aid chemistry will afford anatomy than that presented in the course of this interesting process.† The change produced in the white bands is such as to shew very clearly that they are not truly fasciculi, or aggregations of fibrillæ. The action of the acid on these two elements is identical with that produced on the two tissues to which I have shewn them to be anatomically allied.

To these two elements of areolar tissue are to be attributed physical properties similar to those of white and yellow fibrous tissues, and these will vary greatly in different situations, according to the proportion and mode of arrangement under which the two elements coexist.

Of the areolar tissue of glands.—There appears to be a very prevalent misconception with regard to the quantity of this tissue found in the interior of the large glands, as the liver and kidney. It is imagined that it *penetrates* into every interstice, mingles with the capillary rete, and envelopes the ultimate secreting tubules. It is, however, impossible in the most recent specimen of these organs to discover anything answering to this description. All that can usually be detected is a small quantity accompanying the larger vessels in their course within the organ, and forming septa between its coarse subdivisions. And it would be difficult to suppose a purpose which a more abundant supply could subserve. The capillary network and the secreting tubules by their mutual and intricate interlacement sufficiently sustain one another; no freedom of motion is required between them; there is no force tending to separate them. I am far from saying, however, that the ultimate substance of these glands consists only of simple mucous membrane and bloodvessels. In the interstices of these there are probably nerves and lymphatics, of the mode of termination of which we know nothing, but which seem much fewer than is commonly supposed. There is also more or less of an *interstitial amorphous substance*, hereafter to be described.

In these glands and in the substance of many compound mucous membranes there are to be seen here and there small bodies not unlike cellular tissue in an early stage of its development. They have a bulging nucleus from which they taper to the extremities; and they are much longer and slenderer than the prismatic epithelium. With their nature and use I am at present quite unacquainted.

The lungs seem mainly to owe their extraordinary elasticity to the yellow fibrous element of their submucous areolar tissue. This is spread in great abundance under the whole surface, and much predominates over the white. In the trachea and bronchia it is besides largely developed in longitudinal bands visible through the mucous membrane. In the whole of this region its fibrils take a general longitudinal direction, but branch and inosculate at very frequent intervals, enclosing areolæ of small dimensions. But this element does not cease with the tubes; it is prolonged in the form of branching, arching bands over the basement membrane of the air-cells, which it renders elastic and firmly supports.

* The fibrillæ of true white fibrous tissue are almost precisely similar, and, as I believe, are only produced by the observer himself in opening out his specimen for inspection.

† In the case of the dartos, this procedure detects not only what has just been described, but a third element, hitherto in this situation quite confounded with areolar tissue. This is *non-striated muscle*, at once known by its being loaded with corpuscles, or persistent cell-nuclei. See MUSCLE.

Where mucous membranes are not destined to move on the parts they cover, the areolar tissue beneath them is very scanty. This is the case in the nasal cavities, even in the portions furnished with a great substratum of bloodvessels. But where much motion is required, as where a muscular lamina underlies the mucous, and the enclosed cavity is liable to vary in its dimensions, the areolar tissue is copious, and very similar in its elements and in the size of its interstices to the ordinary forms. Examples of this are seen in the whole alimentary tract.

But it is under the cutaneous part of the mucous system that this tissue assumes its highest developement. Elsewhere its object is to promote freedom of movement, or to confer elasticity. Here it answers both these purposes, and in addition gives a great capacity of resistance against external pressure and violence. The former end is attained by the structure called subcutaneous fascia, which is a large quantity of this tissue in its ordinary form. The two latter are effected by that more condensed part to which the term of cutis has been given. This last is the structure to which the submucous areolar tissue of the intestinal canal mainly corresponds, as may be shown by an examinatioh of the submucous tissue of the mouth, pharynx, and œsophagus, which holds an intermediate place. To describe its modifications in different situations would be to encroach too much on the province of another article (see SKIN), and a few general remarks must here suffice.

The framework of the cutis may be said to consist entirely of a modified form of the areolar tissue. Both elements are enormously developed, but especially the yellow fibrous one. The fibrillæ of this are thicker than elsewhere, and branch and inosculate with great freedom, enclosing interstices open on all sides, and giving passage to the wavy bands of the white fibrous element as well as to vessels, nerves, the ducts of the sweat-glands, the sebaceous glands, and the roots of the hairs. These interstices are in general very close, but they vary with the size of the parts which occupy them. On the deep surface of the cutis the yellow fibrous element changes gradually into that of the subcutaneous fascia, or that of ordinary areolar tissue. It cannot be doubted that the skin chiefly owes its elasticity and toughness to this remarkable developement of the yellow fibrous element.

Topographical view of the mucous system in man.—Referring the reader to the article SKIN for a detailed description of that part of the mucous system, and its immediate dependencies, I shall now proceed to point out some of the more remarkable varieties of the internal tracts. These tracts have been usually comprehended under two general divisions, the gastro-pulmonary, and the genito-urinary. The former is continuous with the skin at six points, the two eyelids, the two nostrils, the mouth, and the anus; the latter at a single one, the orifice of the urethra in the male, and the labia pudendi in the female. Besides these, there are two smaller tracts, the mammary, each of which is subdivided into several, which open separately on the skin.

The description of the *gastro-pulmonary* tract may be commenced at the lips. It covers their inner surface, the cheeks, gums, tongue, and palate, and extends into the labial, buccal, and larger salivary glands, of which it constitutes the chief mass. It passes over the arches of the palate, (where its involutions form the tonsils,)and lines the pharynx, Eustachian tubes, and the cavities of the tympana. Penetrating into the nose by the posterior nares, it lines all the passages and chambers of that organ, and advances along the nasal duct to the lachrymal sac. Thence it may be traced along the canaliculi to the front of the eye, where it takes the name of tunica conjunctiva; covers the posterior surface of the eyelids, a certain portion of the sclerotic, and the cornea, and forms the caruncula, the Meibomian and lachrymal glands. In these complicated portions of its course, the membrane shares more or less in the construction of the five organs of special sense, and is the essential seat of two of them, taste and smell. From the pharynx it spreads in two directions; first, into the larynx, trachea, tracheal glands, and bronchial ramifications, until it terminates by forming the air-cells of the lungs; secondly, into the alimentary canal. Here it lines the œsophagus, stomach, and intestinal tube, as far as the anus, and it penetrates along the excreting ducts of the liver and pancreas, into the inmost recesses of those glands, to form their secreting surface.

The *genito-urinary* tract may be traced along the urethra into the bladder, ureters, and pelvis of the kidneys; and thence into the substance of those organs as far as the Malpighian bodies, the extremities of the uriniferous tubules.. In connection with the urethra, processes pass to the glands of Cowper; and, in the male, into the interior of the prostate, the vesiculæ seminales, vasa deferentia, and tubules of the testes. In the female, the vagina, uterus, and Fallopian tubes receive a lining from it, which, at the fimbriated extremity of those canals, becomes continuous with the serous membrane of the abdomen.*

The very remarkable differences presented to the eye by different parts of this system have been a source of great difficulty to anatomists, who, on other grounds, believed them to be nearly allied; and it would appear that hitherto no satisfactory explanation has been given of the anatomical conditions on which this variety depends. This deficiency I shall now endeavour in some degree to supply. From the examinations I have made, I have been led to consider in a distinct and separate manner the several elementary tissues already mentioned, composing the simple mucous membrane, and

* This remarkable exception to a general fact has long attracted attention. As a mere anatomical difficulty, it has lately received curious illustration from Henle's discovery of the existence of an epithelium on serous and other allied surfaces. But its true explanation can probably only be attained by a study of its morphology, joined with that of its final cause.

lying underneath it; and am come to the conclusion that the most complicated diversities that are met with, admit, when studied in this manner, of being explained and reconciled to a common type of structure.

Peculiarities of the skin, mucous membranes, and glands.

Of the skin.—This is chiefly peculiar in its epithelial element and its submucous areolar tissue. The epidermis is composed of a vast number of superimposed laminæ of scales, which, in the earlier stages of their developement, and especially in certain races of mankind, contain minute *pigment granules* in their interior. The pigment disappears more or less completely as the particles attain the surface. It is continued for some distance down the hair follicles and sweat-ducts, and thus serves to mark the continuity of these parts with the general surface. Hairs, nails, hoofs, and other similar appendages are all composed of modified epithelial particles, and are nearly peculiar to the skin. The sebaceous and perspiratory glands, and the spiral ducts of the latter traversing the epidermis, are also among the most characteristic features of this part of the mucous system. The papillæ of the skin have their counterpart in the villi of the mucous membranes; the cutis *vera*, as it is called, has also its analogue in the submucous areolar tissue, but it is so enormously developed that the resemblance has escaped the notice of anatomists. Its characters have been already briefly described. It is a striking fact that the cutis, like the submucous areolar tissue, contains no fat, even in the most corpulent subjects. I have repeatedly made this remark. The cutis differs in this respect from the subcutaneous fascia, which is therefore, perhaps, to be regarded as less allied to the submucous areolar tissue.

Of the mucous membranes.—These hold an intermediate place between the skin and the true glands. They blend insensibly with the former at the different orifices of the body, and may, under favourable conditions, become so modified as to assume the appearance of skin. The change then wrought is nothing more, however, than an increased deposit of epithelial scales, with an absence of the natural moisture; and it may be doubted whether a transformation of this kind could occur in a mucous membrane of which the epithelium was not of the scaly variety. On the other hand certain parts of the membranes usually termed mucous are nothing less than real glands arranged in a membranous form.

The mouth, pharynx, œsophagus, the vagina and vaginal surface of the uterus, are the parts whose lining membrane most nearly resembles the skin. Their most remarkable feature is the thickness of their covering of epithelial scales, provided for their protection against foreign contact and pressure, and in connection with this the existence of numerous glands opening upon them for the lubrication of their surface. Many of these glands correspond with the sweat-glands of the skin in being similarly scattered under the surface. Such are the buccal and all the small glands allied to them, which, in particular, resemble the largely developed sweat-glands of the axilla. The only difference between them is in the mode of involution of the secreting membrane, which in the former is cellulated, in the latter tubular. These portions of the mucous membranes also approach the skin by the denseness of their submucous areolar tissue.

In the pharynx it is only that part of the lining membrane below the posterior arches of the palate, or that exposed to friction during deglutition, that has the dermoid characters now described: all above is more delicate, is clothed with ciliated epithelial prisms, and belongs physiologically to the nasal or respiratory tract. The lower or buccal surface of the soft palate differs in a similar way from the upper.

The lining membrane of the Eustachian tubes and tympana is very delicate, none of the elementary tissues predominating. The epithelium is in a single layer of prisms clothed with cilia. The submucous areolar tissue is in very small quantity, and the vascular network consists of little more than a simple plane expansion. In the nose, the epithelium, according to Henle, is scaly on the septum and on the alæ for some way within the nostrils. Here also there are hairs—an advance towards the characters of the skin; beyond this it is everywhere ciliated, even within the bony sinuses. The membrane covering these sinuses is of extreme tenuity, and presents the elementary tissues all in a simple form. That covering the pendulous parts of the spongy bones, on the contrary, has long been noted for its great thickness—a character due to neither of the elements of the mucous tissue itself, but to the extraordinary size of the submucous vessels. Both arteries and veins are large, but especially the latter, which here form a plexus immediately beneath the surface, and not separated from it by any considerable quantity of dense areolar tissue. Hence the facility with which these vessels give way externally when distended with blood. The lining of the nose has been sometimes called a *fibro-mucous* membrane, from its close connection with the periosteum. The periosteum in the sinuses is extremely delicate, in consequence of the tenuity of the bony laminæ it invests; and it would perhaps be impossible to separate it there from the submucous areolar tissue. The globe and cornea are covered with scaly epithelium, of which the particles are smaller towards the folds of the eyelids,* where they gradually become prismatic, and along the tarsal borders clothed with cilia, so small as to be only recognizable a short time after death. The conjunctiva of the lower lid is very minutely villous. At the pharyngeal orifice of the glottis, the epithelium becomes ciliated and continues so along the trachea and bronchial ramifications as far as the air-cells, but, according to my own observations, the cilia there cease, and the epithelium changes its character to a remarkable variety of the glandular form. In the air-

* Henle, loc. cit.

passages, as formerly described, the submucous areolar tissue presents a remarkable modification, and is closely joined to the perichondrium of the inner surface of the cartilages. It is worthy of remark that the glands with which the tracheal portion of the membrane is furnished, are not placed, like the buccal, duodenal, and other similar glands, immediately subjacent to the mucous membrane, but on the posterior surface of the trachealis muscle, which is pierced by their ducts. This peculiar arrangement would seem to be accounted for by the deviation from the ordinary form which the submucous areolar tissue here presents, and which renders it ill adapted to give to these irregular-shaped bodies that loose investment which they everywhere possess, and which therefore appears necessary to them.

The mucous lining of the whole alimentary canal below the cardia is the largest and best marked example of what I have termed the compound mucous membrane, being composed of vertical tubes which are truly glands, opening on the general surface. That of the small intestine presents villi also. This entire membrane is very soft and easily torn, because its chief mass consists of an epithelium, the particles of which adhere but slightly either to one another or to the basement membrane, and are everywhere disposed in a single layer. There is moreover scarcely any areolar tissue between its involutions, which have, therefore, little besides the vascular web to sustain them. The submucous areolar tissue is in considerable abundance between the mucous and the muscular coats. (See STOMACH and INTESTINAL CANAL.) The lining membrane of the hepatic and pancreatic ducts is simple, and its epithelium of the prismatic variety.

In the *genito-urinary* tract, the epithelium presents every variety. The fossa navicularis* is clothed with small, flat, or roundish scales, the rest of the urethra with a single series of prismatic particles. The cells of the prostate are lined with spheroidal epithelium, the vasa deferentia with prisms. In the vesiculæ seminales there is a pavement of somewhat flattened granules, and also in Cowper's glands. In the bladder, ureters, and pelves of the kidneys, the epithelium is in the form of longish cells intermediate between the spheroidal and the prismatic varieties. The nymphæ, clitoris, hymen, and vagina are covered with scaly epithelium, and this has been noticed by Henle in cases where the hymen has been entire. Within the neck of the uterus the epithelium becomes prismatic and clothed with cilia, and so continues over the surface of the uterus and Fallopian tubes, and even for some distance over the outer surface of their fimbriated extremities. Beyond this it merges gradually into the compressed cells of the serous membrane. The lining membrane of the Fallopian tubes, as well as that of the uterus, is of a compound nature, especially during gestation, and consists of tubules arranged vertically to the general surface. It is to be observed that the cilia only clothe the general surface, and that the epithelium lining the tubules is spheroidal, or intermediate between that and the prismatic. It is a form of the glandular variety, and bears no cilia.

Of the glands.—The varieties apparent in these organs also may be explained by an examination of the modifications and modes of aggregation of the elementary tissues already mentioned. It may be said, in general terms, that the glands are characterized by their solid form, by the great preponderance of their epithelial and vascular tissues, and by the small quantity of their areolar tissue. It is rare for this last to invest every individual involution of the mucous surface in the interior of a gland; but it usually gives a common covering to the whole organ, as well as less complete ones to those subdivisions of it, termed lobes or lobules, which result from the mode of distribution of the bloodvessels and duct, and are designed for the purposes of package or protection.

Such an investment is usually termed the proper coat or capsule of a gland, and seems to correspond most nearly with the submucous areolar tissue of the compound mucous membrane, as, for example, that of the intestinal canal.

The propriety of these remarks will appear, on a particular application of them. As I before entered somewhat in detail into the internal composition of the liver, it may now be selected for illustration. The epithelium, which in the gall-bladder and larger ducts is of the prismatic kind, becomes bulky and of a flattened spheroidal form, in the lobules. It there also acquires a peculiar character, viz. numerous minute globules of an oily or fatty nature, disseminated within the substance of each particle. The basement tissue seems to cease, and on an examination of a thin section of the lobule under a high power of the microscope, its chief bulk appears to consist of epithelium. There is scarcely a trace of areolar tissue to be anywhere detected. Even the coats of the capacious capillary bloodvessels, in the close meshes of which the ultimate ramifications of the bile ducts are situated, are with difficulty seen, and are of extreme delicacy. The submucous areolar tissue of the hepatic ducts, with which the whole of the contiguous capsule of Glisson should be associated, cannot, when arrived at the lobules, be followed into their interior. It can only be distinguished in very slender quantity, giving them a partial investment, on those aspects which share in forming the portal and hepatic-venous canals, and where, in the angles of union between three or more lobules, a terminal twig of the portal vein runs up to open on all sides into their capillary plexus. No lobule is isolated from the rest by a complete capsule, but communicates immediately by its capillary network, with those near it. The intralobular vein has a similar want of areolar tissue around it; and thus the main mass of the lobule, and of the whole liver, consists of epithelium and a plexus of capillaries. Those lobules, however, which contribute to form the general surface of the

* Henle, loc. cit.

organ have an additional and dense covering of areolar tissue on that surface: a covering, which has the same relation to the mucous element, as that on the portal aspect; which is continuous with the capsule of Glisson at numerous points; and which is here developed as a membrane of support, as a nidus for a lymphatic rete, and as a foundation for the peritoneal tunic, that it sustains.

The nerves and lymphatic vessels of the interior of the liver, though but little known, are too inconsiderable in point of size to affect the general accuracy of this description. Hence it evidently appears, on what modifications of the elements of the mucous tissue and of those appended to it, the peculiar friability, colour, and other properties of this organ depend. If the "parenchymatous" areolar tissue abounded in this gland to the extent implied in the descriptions of Bichat and some more recent authors, no doubt its toughness would be far greater than it really is. But where an organ is sufficiently screened from injury by its position, where its different parts are so well connected by the continuity of a close network of capillary vessels, and are not required to move on one another, it would be difficult to imagine what purpose a greater development of areolar tissue would serve.

In the *kidney*, the epithelial and vascular elements are in corresponding abundance, the areolar tissue in very small quantity. The general texture, however, is more tough than in the liver, from the universal presence of the basement membrane on the tubes. In the medullary portion, the tubes radiate from the apex towards the base of the cones, and are imbedded in a firm, granular substance, not hitherto described, but which resembles a blastema, and is probably composed of cells. In this substance is also imbedded the capillary plexus surrounding the tubes, as well as the vessels that convey blood to and from this plexus, and take the same direction as the tubes. Hence the firmness and close texture of this part of the kidney as compared with the other, and the facility with which it tears from the apex to the base of the cones. At the base of the cones, the tubes enter the cortical substance and take a course, in sets, towards the surface. The central tubes of each set reach the surface and then recline inwards and become convoluted. But the others bend down one after another and become convoluted before reaching the surface. All at length terminate in the Malpighian bodies, which lie among the convolutions. The arteries and veins also take a general course from the hilus towards the surface. Hence, on tearing the cortical part of the organ, there is a disposition for the laceration to occur in lines continuous with the radii of the medullary cones, and this disposition is less evident as we approach the surface; but between these lines the torn surface is very uneven, where it is formed by the contorted tubes. The cortical part has less of the intertubular matrix than is met with in the medullary cones.

In the kidney there is a peculiarity of the highest interest in the relative situation of the vascular and mucous tissues, which seems to have reference to the peculiar function of the gland. There are two systems of capillary vessels, the former of which, or that in connection with the renal artery, perforates the mucous membrane at the extremity of each tube, and lies on the outer surface of the membrane, that is, bare and loose within the dilated extremities, which thus form the capsules of the Malpighian bodies.* (See REN.)

The common submucous areolar membrane of the kidney, or that forming its capsule, is in most animals chiefly composed of ordinary areolar tissue with close meshes. But where a more resisting covering is required, as in the lion, this areolar tissue is modified; the white fibrous element predominates so much as to give the capsule the glistening aspect of an aponeurosis. This is an admirable example of the transition from areolar tissue into white fibrous tissue, and helps to show the true nature and relations of the tunica albuginea of the testis.

The *testis*, compared with the liver and kidney, presents several modifications of the elementary tissues. The basement membrane is much stouter than in the latter gland, the tubes are larger and their convolutions more loosely joined by any intervening substance. There is no appearance of an intertubular substance except towards the corpus Highmorianum, and the principal connecting medium between the tubes seems to be the vessels, which are less numerous than in the glands already mentioned, and form a looser network. The secreting tubules for these reasons admit of being very easily separated from one another, and unravelled to great lengths. The epithelial element of the testis constitutes a lining of considerable thickness, and is highly remarkable (see *fig.* 274). Though no seminal animalcules have been hitherto seen in the interior of the particles while still attached to the basement membrane of the tubes, yet from recent researches, and especially from those of Wagner, on the phases of their development, it is rendered highly probable that these singular moving bodies originate in the epithelial particles, as one of the results of their natural evolution. The loose aggregation of the tubules of the testis makes a firm external capsule necessary, and where, as in man, this gland is much exposed to injury by its situation, a further protection of this kind is made requisite. Hence the firm and unyielding character of the tunica albuginea in man, the contrast of which with the thin covering of the large but well protected testicle of the porpoise (for example), is well worthy of attention. In many large animals, the tunica albuginea, like the aponeurotic capsule of the lion's kidney, is traversed more or less completely by large veins which it thus serves to support. The tunica albuginea consists almost solely of white fibrous tissue, and represents the submucous areolar tissue of the mucous system.

The peculiarities of the *salivary glands* re-

* Phil. Trans. 1842, part I.

sult from the predominance of their epithelial element over the others. The ducts terminate in vesicles, very similar in the figure they assume to those of the lungs, but nearly filled up with epithelial particles. The basement membrane is very delicate. The capillary vessels encircle the vesicles, and are comparatively few in number, whence the pale colour of these glands. The areolar tissue forms capsules for those aggregations of vesicles, termed lobules, but does not penetrate between the individual vesicles.

The *mammary glands* derive their extreme denseness and toughness, as well as their white colour, principally from the areolar tissue, in which the proper glandular membrane is enclosed. This tissue penetrates more abundantly between the minuter subdivisions of the gland than is observed in any other instance. It thus affords support, at the same time that it permits and facilitates movement of one part of the organ on another. It is also of such a nature as to readily allow of distension during lactation.

General outline of the functions of the mucous system.—By its external anatomical position, this system is subservient to four great functions: the reception of impressions from without, the defence of the body from external injurious influences, the absorption of foreign particles, and the separation of such as are for any reason to be eliminated. It may almost be said to be the peculiar seat of these functions, which, however, are distributed in a very unequal manner over its different regions.

Reception of external impressions.—The skin and mucous membranes appear everywhere fitted by their nervous supply to receive impressions, which, being conveyed to the nervous centre, may there excite a reflexion of stimulus along motor nerves, without the intervention of consciousness. Common sensation, or that which in its most exalted form becomes touch, exists in all parts of the cutaneous surface, within the mouth, for some distance within the nostrils, and (with the exception of the pharynx and œsophagus) in general, wherever the epithelium is of the true scaly variety. Where the sense of touch is most perfect, the simple membrane is observed to be involuted into the form of papillæ for the purpose of crowding a larger number of nervous loops into a given space. Taste and smell, which are nearly allied to touch, are the other special senses of which the mucous system is the seat. The sensations of hunger and thirst seem also referrible to this tissue.

Defence from external influences.—One chief division of the mucous system, viz. the skin, derives its main characteristics from its adaptation to this function, and those parts of the mucous membranes which are most exposed to the contact of irritating substances approach the most nearly to the skin in their structure. Their epithelium is scaly and in thick laminæ, their submucous areolar tissue abundant, dense, and resisting. The nervous endowments of such surfaces, whether excito-motory or sensorial, mainly contribute to the protection of the animal. And, on the external tegument, the developement of hairs, nails, &c. in their endless modifications of form, position, and structure, serve, with few exceptions, the same important purpose. In some parts of the mucous membrane peculiarly obnoxious to pressure, there are special glands for the lubrication of their free surface.

Absorption of external material.— Every particle, entering the body from without, is absorbed, in the first instance, through some portion or other of the mucous system. What is now known of the nature of this function in general, renders it certain that every part of the mucous system would form an absorbing surface, if favourably circumstanced for doing so. But as the extraneous material, to be absorbed, must be brought into contact with the absorbing surface, often by some special and complicated means, this function is chiefly limited to certain distinct districts of the system. With few exceptions the glands are not suited either by their position or structure to receive the contact of extraneous substances, and even many portions of the mucous membranes are incapacitated in the same manner, as, for example, most of those lining the excretory passages of the glands. The secretions which, in a healthy state, are the only substances brought into contact with these surfaces, are, it is true, occasionally modified by a partial absorption of their constituents; but, generally speaking, this occurs to a very slight extent. Once formed, they usually traverse the channels, leading to the outlets of the body, unchanged.

The simplest condition under which this function presents itself appears to be that exhibited by the respiratory surface, which, whether it be arranged as lungs or gills, is concerned with aeriform particles, and absorbs and secretes through the self-same structure. The skin also is a very active absorbing surface, and appears, by the best observations, to be provided with a close net-work of lymphatics, which I have already stated to be most probably situated immediately under the basement membrane. It does not appear that the existence of the lymphatic pores, described by MM. Breschet and Roussel de Vauzème as opening on the free surface of the cuticle, has been confirmed by any subsequent anatomist. I have sought in vain for any such system of vessels in the cuticle, and I believe those distinguished observers must have been deceived by the irregular lines of union between the epidermic particles. It is true that the thickness and texture of the layers of epidermic scales are little calculated to allow of their being permeated by foreign material, whether fluid or gaseous; and, therefore, it is not likely that absorption is effected to any great extent either through their substance or interstices. It seems more consonant with facts to suppose, that this process, especially in respect to solid matters, is carried on by the simple membrane of the sudoriferous ducts, with which external particles would easily be brought into contact through their open extremities. But as these ducts traverse the thickness of the cuticle, and in that part of their course have not (in man) any proper wall, but are bounded only by the edges of the scales between which they pass, it is very probable that the deeper and softer laminæ of epidermic particles may not merely be moistened by the secretion of the ducts, but, under favourable circumstances, may borrow extraneous matters from them, and thus become a part of the absorbing medium. In reference to the question of absorption by the skin, it is interesting to notice the modification of this structure in those lower animals in which this function is manifested in much greater activity than in man. A better example cannot, perhaps, be selected for this purpose than that of the frog. Its epidermis consists of a single layer of scales, and in consequence they do not overlap, but join edge to edge. These scales are not reduced to mere membrane, but always contain a considerable quantity of fluid in their interior. The sweat-pores open here and there in the interstices between three scales, and have true walls, formed out of a pair of modified epidermic particles, adapted to one another, and elongated into the subcutaneous texture. They thus bear a very close resemblance to the *stomata* of leaves. I lately discovered this singular arrangement in the cast-off cuticle of the animal. It seems undeniable, that, here, absorption is effected by the whole series of epidermic scales, as well as by the pores.

But the most remarkable, and at the same time the most recondite form, under which this function is exhibited in the mucous system, is that met with in the alimentary tract. Here, indeed, water and aqueous solutions are imbibed, with great rapidity, into the vascular plexuses of the blood and lacteal systems, as the united testimony of many able experimenters abundantly shews. But from this merely physical process of *imbibition* is to be distinguished the more mysterious and elective function of chylous absorption, which is conducted by the lacteals alone, and is consequently limited to the region supplied with that system of vessels. For an account of the present state of knowledge on the highly important subject of the intimate nature of this function, the reader is referred to ABSORPTION and LYMPHATIC SYSTEM, in which he will find the chief of the conflicting statements and opinions of physiologists detailed and discussed. It has already been explained in the present article, that the latest observations on the structure of the villi, and apparently the most exact ones, because conducted with the most improved lenses, and accordant with other collateral discoveries, make it highly probable that the opinion assigning open mouths to the lacteals is erroneous. In the description of those orifices, furnished by Treviranus, we may plainly discern his partial acquaintance with characters which we now know to be those of the prismatic epithelium investing the villi; and the less precise assertions of the same kind by several other excellent anatomists, we may now, perhaps, fairly consider to have been founded on deceptive appearances which, in their day, did not admit of accurate interpretation. If any such orifices exist, their minuteness must be extreme, and they must lie in the intervals between the prisms of epithelium. But even such attenuated pores, the best microscopes fail to detect, and at least it may with certainty be affirmed, that none large enough to admit a chyle-globule exist. The structure of the villi, no less than our knowledge of the absorbent function in general, seems to indicate that the chyle, when first taken up, is strictly a fluid, and only acquires its solid particles after it has entered the lacteal plexus.

Of the separation of material from the body.—This function appears to be carried on in every part of the mucous system. One great division, that of the glands, is specially destined to it, as are likewise those portions of the compound mucous membranes, which have been already described as coming properly under the designation of glands. If, however, the essential nature of the function of secretion be adequately considered, it will scarcely be doubted that even the simplest parts of the mucous membranes, and the whole cutaneous surface (as distinguished from its sebaceous and perspiratory glandular offsets) share largely in this important office. It is true that in the skin this function holds a subordinate place to that of defence and protection, but its existence is only an example of what an attentive survey of nature everywhere discovers; the accomplishment of various ends by means of the same simple instruments.

The notion that a secreted product must be fluid, is one that has arisen out of a partial and imperfect insight into the nature of the secreting process. Those matters which are eliminated in the largest quantities and by the largest glands are for the most part so, in the shape under which they meet the eye, that is, after their separation from the organ in which they are secerned. But in the case of the lungs the secretion is gaseous as well as fluid, and in numerous instances, which have been recently brought to light, chiefly by the labours of Henle, it is found, when minutely scrutinized, to consist of organic forms entitled to be styled solid.

The problem which physiologists have now to resolve, is how far these organic forms, which are more or less altered epithelial particles, are necessarily concerned in the performance of the function, for epithelium is all but universal in the mucous system. It would be foreign to the province of this article to enter at length on the general question of secretion, and I shall confine myself to a few remarks tending to show in what direction recent researches point.*

When the secretion of a sebaceous follicle of the skin is minutely examined, it is found to consist entirely of epithelial particles containing the sebaceous matter, and more or less broken and compressed. These are similar to the particles lining the follicle, and are mani-

* Purkinje, Isis 1838, No. 7. Schwann, Froriep's notiz. Feb. 1838. Henle, Müller's Archiv. 1838, p. 104-8, 1839, p. 45; also Müller's Phys. by Baly, 2nd edit., vol. i., p. 503-4.

festly the same structures, detached and matted together. The secretion found in the tubules of the testis is chiefly composed of epithelial particles resembling those attached to the basement membrane of the tubules. Some of these are very perfect, others have undergone changes. It has been already stated that the seminal animalcules are most probably a developement of some of these particles, not altogether different in its nature from that of the cilia found upon them in other situations. The secretion of an ordinary mucous follicle is likewise made up of epithelial particles resembling those still attached to the membrane. The thick, semifluid mucus found in the stomach has been shown by Wasmann* to consist of rounded nucleated particles, which both in size and shape correspond with those of the stomach tubules. This mucus may be even seen projecting from the cells into which these tubules discharge themselves, and no doubt can exist that the proper secretion of this organ is chiefly composed of the bulky epithelium thrown off by the tubules; a view corroborated by the fact,† that this mucous membrane, consisting almost solely of epithelium, when mixed with certain acids naturally existing in the gastric juice, evinces the same powers of dissolving alimentary substances as that wonderful menstruum itself. The same thing may be observed in the intestinal canal, where the adhesive mucus is little else than the aggregated epithelial caps of the villi, together with that which has escaped from the vertical tubes of the membrane. These facts may be always verified in a healthy animal just killed, and may thus be shewn to be independent of any morbid action. The legitimate conclusion from them seems to be this: that the peculiar principles of these respective secretions are lodged in the epithelial particles; having been deposited there from the blood, in the natural course of developement. In other words, the process of secretion in these cases consists in *an assimilation of the material from the blood by an organized tissue*, which, when fully developed, is loosened and shed.

This view, so captivating by its simplicity, has certainly much satisfactory evidence in its favour, and it may, at least, be regarded as sufficiently established to constitute a strong presumption in favour of the general position, that *all secretion is primarily assimilation.*

That the epithelial particles, when their growth is completed, should detach themselves in a more or less entire state, in all cases, from the membrane to which they have adhered, cannot be supposed essential to this general position, and even the total absence of any vestiges of these particles from any particular secretion would scarcely form a valid argument against it. For at present we know of no reason why the assimilated material should not be gradually given up by a slow disintegration or deliquescence of the particles, or even by a continual separation of it without a concomitant destruction of the particles themselves.

But in numerous instances besides those that have been mentioned, there is more or less direct evidence of an actual shedding and continual renovation of the epithelium. The scaly variety of this tissue, whether on skin or mucous membranes, is a wide-spread example of this: the particles may be observed to augment in size by the intus-susception of new material from the blood, afterwards to undergo a slow loss of substance, and, finally, to lose their connection with the body altogether. They retain their position till nothing but the nucleus and cell-membrane remain, till they are reduced, as it were, to a mere skeleton. How the material thus separated from the body is to be distinguished from a secretion, it would not be easy to decide. In the saliva of the mouth, are present, not only detached scales, but globular nucleated particles, of a very delicate aspect and regular character, which seem manifestly to come from the salivary glands. They differ in some respects from the epithelium of these organs, but appear most probably to be particles of it altered by endosmose of the water of the secretion through the cell-membrane; for the ultimate vesicles and ducts of these glands are not merely lined, but filled, with epithelial particles, which, being thrown off from the basement membrane, must in due time escape to make room for the advancing series: and yet none of them in an unaltered state are found in the saliva.

I may in this place refer to an opinion recently entertained in Germany, that the secreting membrane of certain glands is arranged in the form of closed vesicles filled with nucleated particles, which, from time to time, are discharged, as the secretion, by the bursting of the cell in which they are contained. Henle* conceives that this arrangement exists in the mammary, salivary, and lachrymal glands, as well as in almost every mucous membrane, however apparently plain and simple. Wasmann† has described a similar structure in the middle part of the stomach of the pig. This view of the existence of closed vesicles is obviously at variance with the general view before given of the universal continuity of the simple membrane of the mucous system. I am familiar with many of the appearances on which it is founded, and without presuming to pronounce them very decidedly deceptive, I may state that hitherto my observations induce me to agree with Dr. Baly‡ in his rejection of the interpretation put upon them by the German anatomists. A thin slice of a mass of the many-lobed terminal vesicles of one of these glands, especially if compressed, very readily assumes the aspect of a congeries of cells, each entirely surrounded by an envelope of basement membrane. But I have several times, in favourable sections, observed this membrane passing off into a neck, and becoming con-

‡ Translation of Müller's Physiology, p. 504.

tinuous with that of the duct. Such observations seem to me in a great measure conclusive on this subject; and I am strengthened in this view by the fact, that the capsules of the Malpighian bodies of the kidney are now universally considered to be perfectly closed vesicles, whereas they are in reality the expanded wall of the duct, as I have lately shown by several kinds of proof.* But whatever may be the real fact in the matter under dispute, it is admitted by all that the epithelium is formed in enormous quantities, and is being continually thrown off; which is the circumstance chiefly intended to be insisted on at present.

In the healthy bile also, in the urine, and in various other secretions Dr. Henle has met with particles of epithelium detached from the *excretory passages*, and in different stages of decay.

Turning to those two great emunctories, the liver and kidneys, in the secretions of which no trace of the epithelium of the secreting part of the organs can be detected, we might be disposed, on a slight consideration, to conclude the evidence they furnish to be unfavourable to the general position here advanced. We must, indeed, be content for the present to acknowledge that it is less plain and direct, and shrouded in our great ignorance concerning the play of chemical affinities in living bodies; but still it is too interesting and important to be passed over in silence. Though the epithelium of these organs be not detached entire, as in many other cases, there is much, in each instance, to explain the discrepancy consistently with the theory in question.

I have described the lobules of the *liver* as consisting of a solid plexus of capillary bloodvessels, in the meshes of which is a congeries of epithelial particles. We possess no accurate account of the mode of termination of the biliary ducts; but it seems clear, from the small meshes of the vascular plexus being completely filled by the epithelium, that no true ducts, i. e. tubes, penetrate the substance of the lobules: the tubular ducts probably commence on the surface of the lobules. The epithelium of the lobules is doubtless continuous with that of the ducts, but the cavity of the ducts and their basement membrane terminate at the surface of each lobule. Though the cavity of the ducts be not continued within the lobule, yet it is very possible that injection urged along the ducts might insinuate itself by the side of the epithelium into the interstices of the vascular plexus, and thus, like the epithelium itself, form a solid plexus within the lobule. This appearance probably led Mr. Kiernan to describe the termination of the ducts as forming a plexus within the lobule, the *lobular biliary plexus*. And this description must be allowed to be essentially correct; for although the cavity of the duct cease at the surface, the epithelium of the lobule is, in respect of function, its real continuation. I have further observed, that although the epithelium of the lobule has, on the whole, a plexiform arrangement, yet its particles in some measure affect a radiating direction from the central axis towards the circumference, perhaps towards certain parts only; and when a lobule is broken up by violence, the resulting fragments of epithelium are apt to consist of a linear series of particles. Many of the particles, too, are smaller than the rest, and have all the appearance of having been recently formed and as yet incompletely developed. It is also remarkable that the particles should contain granules of oily matter in their interior; for although chemical analysis has detected differences between this substance and cholesterine,* yet as the chief peculiar principles of the bile are forms of hydro-carbon, the coincidence cannot be an accidental one. It is not contended that the contents of these particles are the finished secretion, but rather that their chemical constitution undergoes some modifications during the disintegrating process. And it is worthy of notice, that in many cases where the decarbonizing function of the lungs is slowly but greatly interfered with, as in phthisis pulmonalis, and where the liver is consequently called into increased activity as a compensating organ, these oily globules exist in such abundance and size as to gorge and swell the particles (and therefore the whole viscus) to nearly double their natural bulk.† But this is not all the evidence, that this epithelium is the source of the bile. I am informed by my friend, Dr. W. Budd, that Dr. Henle in his recent edition of Soemmering, of which I have not yet been able to obtain a copy, describes the epithelial particles as appearing yellow or yellowish brown in direct light, and as probably containing bile. He also states that the presence of the fatty globules in the epithelium is inconstant, and corresponds with the varying fatty contents of the bile. He is unable at present to determine in what manner the contents of the particles find their way into the ducts.

The foregoing facts, taken together, afford a very strong presumption that the epithelial particles of the lobules are the agent assimilating the secretion from the blood. It would be still more satisfactory if particles could be found undergoing decay. Meanwhile it seems impossible to assign to them any other office, if it be granted that the sole function of the liver is to secrete bile. For in the case of other glands, the only other use that can with any degree of plausibility be attributed to the epithelium is that of its serving to defend the secreting membrane from the contact of the secretion, and to prevent the latter from reentering the blood. And it cannot exist for that purpose in the liver, because it is itself the only structure besides the bloodvessels, and does not constitute a lining membrane.

The peculiarity in the minute structure of the *kidneys*, which bears on the present question, is of a kind entirely different from any presented by the liver, and yet tends to establish a similar conclusion. It consists of a special

* Kuehn, Kastner's Archiv. xiii. p. 337.

† Author in Lancet, Jan. 1842.

apparatus at the extremity of each secreting tube, apparently designed to furnish a flow of water down the canal.* A large quantity of water is evidently required in this secretion as a menstruum for the salts and proximate principles it contains; and there is no doubt, from the analogy of other glands, that the walls of the tubes are the membrane secreting these substances. Now the epithelium constitutes at least $\frac{19}{20}$ths of their thickness, and is the only part of them with which the water can come into contact. It therefore seems highly probable that this fluid is provided in the manner described, in order to dissolve, out of the epithelial particles, the peculiar principles which they have previously assimilated from the blood.

In support of this general position it may be observed, further, 1. That the epithelium, which constitutes so large a portion of the true glands, is solid and bulky, usually characterized by its finely granular texture, and in this respect contrasts strongly with that lining the vascular system, which is of extreme delicacy and transparence. The exceptions to this remark confirm its importance. In the air-cells of the lungs, the secretions of which are gaseous and not solid, the epithelium is of great tenuity, and in the Malpighian capsules of the kidney, which appear to serve principally as receptacles for the aqueous fluid that escapes from the bare capillaries within them, this structure is either wanting or consists of perfectly transparent particles. In many intermediate varieties, too, there appears traceable a correspondence between the bulk of the nucleated particles and the activity of the secreting function; of which the scaly form in general may be mentioned as an instance. 2. That many peculiar substances are secreted into the interior of nucleated cells, although prevented, by the position of those cells, from escaping from the body. Such are various fats and fixed oils, colouring matters, &c. 3. That this function of abstracting somewhat from the blood, and elaborating it, seems the most probable one that can be assigned to the thymus and thyroid bodies, the spleen, and supra-renal capsules, and specially to the nucleated particles forming so large a portion of these several structures. On the whole there seems much weight of evidence in favour of the proposition "that secretion is a function very nearly allied to ordinary growth and nutrition: that whereas these are a combination of two functions, assimilation of new particles and rejection of old, the old being reconveyed into the blood, secretion consists in a corresponding assimilation and rejection, but the old particles are at once thrown off from the system without re-entering the blood. According to this view, all effete material received into the blood, from the old substance of the various organs, must be reassimilated by an organized tissue, specially designed for the purpose, viz. the epithelium, before it can be eliminated: and all substances thrown off from the system, but designed for an ulterior purpose, must in like manner be assimilated in order to their separation." It places in a strong light a principle of great importance in physiology, the subordination of the bloodvessels and their contents to the tissues among which they are distributed.

The function of secretion may therefore be considered to be universal over the mucous system, and its different activity in various situations to be dependent on, as it certainly is closely associated with, differences in the arrangement and structure of the epithelial element. The basement membrane, from being absent from the lobules of the liver, seems a tissue of inferior (perhaps of no) importance in respect of this function, and probably is chiefly subservient, wherever it exists, to the mechanical support of the epithelium.

There are probably *three ways* in which the secretions are finally separated from the body: and these three ways appear to have a reference to the chemical qualities of the product, and to their effete or non-effete character. 1. The particles assimilated into the nucleated cell may be thrown off by virtue of minute chemical changes occurring in it, without the cell itself being altered in form. In this case the nucleated cells will be permanent, or only very slowly renewed, and the secretion will be formed, or at least perfected, by the passage of its elements through the cells. 2. The nucleated cells, as they arrive at their full size, may undergo a slow change in the arrangement of their elements, and gradually disappear by a kind of solution or deliquescence, thus forming the secretion. 3. The nucleated cells, when mature, may be cast off at once, and entire, with their contents. The two last modes are attended with a continual formation of new cells.

It would appear that, in general, where the secretion is formed by the rejected chemical elements of the cells (1), or by the destructive solution of the cells (2), it is *effete;* but that, when formed chiefly by the separation of cells that are mature and contain much organic matter (3), it is *destined for ulterior purposes in the œconomy*. Of the first the kidney seems to be an example, of the second the liver, of the third the lining membrane of the stomach.

The varieties in the *qualities* of the products secerned by different portions of the mucous system are only referrible to varieties in the elective powers of the tracts which respectively furnish them, and admit of being most readily explained by the view of the nature of secretion already advanced. It is unnecessary, in this place, to enter on a particular description of the boundaries of these several tracts, and I shall only offer a few observations on the nature and extent of that secretion which has given its name to the structures here treated of.

The term *mucus*, like so many others transmitted from an early period, was originally employed to denote an exaggerated and partial condition, was subsequently applied more loosely and widely in a generic sense, and now requires to be reduced to a more definite

* Phil. Trans. Pt. I. 1842, p. 73. See also the article REN.

application in accordance with that necessity for precision of thought and expression which characterizes modern science. The exposition contained in the article Mucus will render it superfluous for me to define its present acceptation. It is denied by Dr. Gruby that the viscid form of mucus is a normal secretion from any membrane whatever, and he considers its existence as a certain mark of diseased action. This view, if less absolute, would be in a great measure correct, since there is no doubt that in a state of perfect health most mucous surfaces are wholly unprovided with any protection of this kind. If the nasal cavities, the trachea or bronchia, the intestinal or urinogenital tracts, be examined in a healthy animal killed for the purpose, we may search in vain for any slimy covering, such as they are commonly imagined to possess. But in a state of disease, each of these surfaces will secrete great quantities; and it is not a little remarkable, that, even when healthy, if moistened and allowed to undergo slight putrefaction, they will become coated with a viscid fluid, having the physical characters of mucus. Yet the slimy fluid of the mouth cannot with propriety be considered abnormal. The true saliva is not viscid, as it escapes from the ducts of the glands into the cavity of the mouth: it probably becomes so by dissolving the substance derived from the scales of epithelium lining the mouth, as they advance to the surface and flatten. The fluid of ranula is not merely the accumulation of a natural secretion, but seems gradually to acquire its great viscidity by receiving the debris of the epithelium lining the excreting channels, and by the partial reabsorption of its aqueous portion.

In the intestinal canal, however, although there is no viscid mucus naturally present, yet there is a large amount of "inspissated mucus" being continually separated from the villi and follicles of Lieberkuhn. This mucus, as already mentioned, is nothing more than the debris of epithelial particles.

But chemists have detected, in most of the secretions, a small proportion of a substance nearly allied to mucus, and probably a form of it. There is good reason to believe this to be the product of the membrane lining the excretory passages, and to represent the old epithelium of that membrane. Where the secretion of the gland is fluid and in considerable quantity, it seems to be sufficient to convey away this debris from the surface which it traverses on its way out of the system, as in the salivary and allied glands, the liver, kidney, &c. But where, from the absence of this means of carrying off the debris of the epithelium, it might be supposed to be liable to accumulate and clog the surface, cilia are developed; of which the best example is furnished by the respiratory tract, the nasal cavities, and the tympana. That this is the great office of these wonderful organs upon these extensive surfaces appears to be proved by the fact that the currents they produce are uniformly towards an outlet. Henle has observed this in several parts, and I have ascertained it by experiment in the case of the tracheal and bronchial membrane.

In this tract no secretion is visible with the naked eye, but with the aid of the microscope I have found, in perfectly recent animals, minute globules of extreme tenuity and of various sizes, which had all the appearance of mucus oozing from the interstices of the epithelial particles. It is impossible but that the cilia should move these globules along the surface, and discharge them into the pharynx; and it hardly admits of doubt that mucus, morbidly existing on the bronchial membrane, is gradually lifted up by these untiring agents to that region where it excites coughing, and is forcibly expelled by the rush of air. The patient is often conscious of its slow motion upwards, when it is in the form of a pellet and proceeds from an isolated spot. This is remarkably the case too in hæmoptysis, and also in that rare disease the bronchial polypus, where branched tubes of lymph are brought up in this manner.

This view of the use of cilia in the mucous system of the higher animals appears to me to merit much attention. I had intended to have considered it under a separate head, but it has been introduced here both in corroboration of the general position as to the nature of secretion, and in illustration of the nature and extent of the special secretion from the ordinary mucous membranes.

On the whole I think it may be concluded:

1. That every part of the mucous system, where epithelium exists, secretes.

2. That the secretion differs, in different regions, according to the vital properties of their epithelia; and that these vital properties are usually attended with appreciable varieties of structure. That corresponding varieties of chemical constitution coexist with these is highly probable, though only as yet proved in a few cases.

3. That mucus is the least peculiar of the secretions, yet by no means universal from the mucous membranes, but confined to tracts of comparatively limited superficial extent, chiefly the excretory channels of the glands.

In the preceding summary account of the structure, relations, and offices of the mucous system, I have not been able (without interruption to the course of the description) to refer sufficiently to the labours of those anatomists to whom we owe almost all our knowledge of the subject. This deficiency, of which I am very sensible, I shall endeavour in some degree to supply by a brief review of the researches which have led to the more modern and general views on the subject. Passing over the imperfect descriptions of the ancients, we find that when the microscope first became an instrument of anatomical research, the scaly character of the cuticle was recognised by Malpighi and Leeuwenhoeck; and that the former of these great anatomists had a wonderfully clear insight, considering the period at which he lived, into the close relation that subsists between the glands, mucous membranes, and skin. The labours of the anatomists of the next age were spent with great success upon matters of detail, particularly on the distribution of the blood-vessels, which Ruysch and Lieberkühn particularly illustrated; and, by the general advance of knowledge, the way was being gradually prepared towards that more philosophical arrangement of the tissues of the body, in conformity with their intimate texture and connexions, of which the first example is to be found in the work of Bonn,* already alluded to. He here traces, with great accuracy, the continuity of the skin and mucous membranes at the different orifices of the body, and he clearly recognises their close structural relation, considering the mucous membranes to be productions of the skin. To our countryman, Dr. Carmichael Smith,† we are indebted for the first application of this arrangement to the purposes of pathological classification, and Pinel soon after followed in the same track.‡

But a new era dates from the remarkable works of Bichat,§ in which he delineated the structure, vital and other properties, and the relations of the different tissues of the body, and arranged them on a basis, which, though faulty in some of its details, has received no essential modification in its principles since his time, and entitles him to the praise of rare genius and sagacity. He seems to have clearly perceived the true connexion that exists between the skin, mucous membranes, and glands, although he failed to carry out his views into the subdivisions of his system, where he was still fettered by the crude notions of his predecessors. One of the most remarkable features in his work, bearing on the present subject, is the analogy he draws between the epidermis of the skin and the mucus of mucous membranes, an analogy which he discovered with the eye of the mind, which has been since often rejected, but which can now be shewn to be real by the eye of sense.

Most writers of eminence since the time of Bichat have adopted the principal part of his views, and some have advanced further towards a full recognition of the homology of the skin, mucous membranes, and glands, among whom must be mentioned, in particular, J. Müller, whose classical work on the glands,|| published in 1830, placed him at once in the foremost rank among the anatomists of our own day.

Subsequently to that date, the improvements in the construction of the microscope and the consequent employment of greater magnifying powers, have added an extraordinary stimulus to anatomical and physiological studies, and directed a host of inquirers into an almost unexplored field, from which the harvests already reaped give the most favourable earnest of future and rapid additions to the stores of knowledge. To the Germans is unequivocally due the merit of having far outstripped all other nations in the honourable path thus opened, and in no collateral path of inquiry which has been pursued to the same extent, has so much new, interesting, and important information of an accurate and satisfactory character, been obtained, as in that which it has been my duty to treat of in the present article. The names of Purkinje, Valentin, Henle, and Schwann deserve primary honour in this place, and to these may be added those of Ehrenberg, Treviranus, R. Wagner, Boehm, Wasmann, Gruby, and Gerber. Among the French anatomists, MM. Turpin, Mandl, and Donné have contributed much, and our own countrymen have not been behind. Dr. Sharpey, Dr. Sprott Boyd, Dr. Todd, Mr. Nasmyth, Dr. Barry, and Mr. Toynbee, are all distinguished in this field of research.*

In the present article I have endeavoured to combine with all the authentic information I could obtain from these sources, the results to which I have been brought by a two-years' study of the anatomical characters of the whole mucous system. So rapid, however, are the daily advances of knowledge, that it is possible much has been omitted which is already in some shape before the public, and, on the other hand, that a few years may greatly modify the general views that are here set forth. As the anatomical details, however, have been all substantiated by my own observations, except where otherwise stated, I am enabled to speak with more confidence of their correctness.

MUSCLE.—(Syn. Μῦς, *Musculus*, Muscular or Sarcous tissue; *vulgo*, Flesh, Meat.) This term is applied to certain fibrinous contractile organs, either elongated and fixed at their two extremities, or hollow and enclosing a cavity, which in all the higher animals are the seat of the power by which locomotion, circulation, the prehension and passage of food, the expulsion of many of the excretions and of the young, as well as other diversified functions, are performed. It is also used to denote the peculiar contractile material or tissue, constituting the principal and essential portion of such organs. This tissue is always arranged in the form of fibres, which in many minute animals occur singly, each serving the purpose of a perfect muscle. But they are usually aggregated in very great numbers, surrounded with a network of capillary vessels, and connected to one another by areolar tissue. The nervous tissue is universally associated with the muscular, however small may be the quantity of the latter; it is through this that the stimulus to contract is ordinarily transmitted, and, when the mass is great, made to affect simultaneously many contiguous fibres. A muscle is the organ resulting from the union of these several parts.

Muscles are styled voluntary or involuntary, according as they are, or are not, subject to the influence of volition, and they have been usually so classified. But, however convenient these terms may be in the ordinary language of physiology, they cannot be applied, in a strict sense, to the purposes of classification without obvious objections. Many muscles, especially those under the immediate dominance of reflex nervous action, (as the respiratory and sphincter muscles,) partake of both characters, since volition can interfere only temporarily with their contraction; and all muscles, even the most confessedly voluntary, are subject to emotional and instinctive influences, in which the will has no share. The attempt to introduce an intermediate or mixed class, which has been generally sanctioned, while it is an acknowledgment of the imperfection of the arrangement, does not appear to be sufficiently warranted either on anatomical or physiological grounds. If subjection or non-subjection to the influence of the *will* be made the basis of classification, all muscles should be accounted *voluntary* on which this can exercise a direct influence either in causing or controlling contraction, even though such influence be but momentary, and capable of being exerted only while the stimulus excitive of involuntary action is in abeyance.

The voluntary muscles are generally solid organs, while the involuntary are hollow; and, on recurring to the minute structure of their respective elementary fibres, we detect very striking differences between them, those of the former being striped crosswise with very delicate and close parallel lines, which, with some exceptions, are altogether absent from the latter. But these exceptions are of so important a kind as to demonstrate beyond doubt that there is no necessary connexion between the minute conformation of the fibres and their relation to the influence of the will. The muscular coat of the œsophagus often displays the striped structure as far down as the stomach, though the will has no power whatever over its movements; and the heart itself is composed of striped fibres. As the structural differences between these two kinds of fibre are constant, well-marked, and therefore easily ascertained, and as they seem, moreover, to be related to varieties in the activity and mode of exercise of their contractile power, they will be employed as the ground of division in the present article.

I shall first describe the minute anatomy of these two kinds of elementary fibre, and the steps of their development; and, secondly, I shall advert to their mode of aggregation and to the arrangement of the tissues found in connection with them.

a. Of the striped elementary fibres.—These have received the name of Primitive Fasciculi on the erroneous supposition of their being bundles of finer filaments. They may be separated from the tissues associated with them in the compound organ by a variety of means, but as they always constitute the principal mass of the organ, they may be examined without any attempt at such separation. It was a favourite plan with the older anatomists to obtain the fibres apart by submitting them to a long boiling, which destroys the texture of the vessels and filamentary tissue, but at the same time considerably modifies the size, shape, and structure of the fibres. It is in general only requisite to take a small portion of a muscle, as fresh as possible, (but after its contractility has departed,) and to tear it, under water, into fine shreds, with needles. By these means the elementary fibres will be separated from one another, and being in parts irregularly broken, and torn, can be submitted to inspection under a high power of the microscope, in such a condition as to exhibit most of the important points in their structure. Many sedulous examinations of specimens from various sources are requisite for the acquirement of a correct idea of their organization and properties, but that this simple method of procedure is the one most likely to lead to a true insight and conclusion regarding the anatomy, not only of this but of all elementary structures, becomes every day more evident. Various subsidiary means may doubtless be employed with advantage, such as injections and physical and chemical agencies; but the method which of all others is the least liable to admit of erroneous interpretations by the admixture of artificial elements in which the mind of the inquirer has had a share, is that of employing a power capable of reaching the utmost limits of organization, on examples the most nearly approaching to their natural state during life.

There is perhaps no one line of inquiry in the whole range of minute anatomy so beset with difficulties and sources of error, and therefore so much demanding a cautious study and sagacious discrimination between conflicting appearances, as this of the structure of the striped fibre. The following description is substantially the same as that published by me in the Philosophical Transactions, 1840, and which all my subsequent observations have tended to confirm. To that paper I would venture to refer those who may desire to enter at greater length upon the grounds of the view here summarily given.

1. *Length.*—This varies exceedingly in different muscles. The sartorius, the longest in the body, often surpasses two feet in length, and the individual fibres are as long, extending in parallel bundles from end to end. In many others they do not exceed a quarter of an inch; thus their greatest variety is presented in their length.

2. *Thickness.*—This should be examined in the uncontracted state of the fibre, which for this purpose should be removed from the body after all contractility has departed. I have elsewhere* given a table of numerous comparative measurements in various animals, and subjoin the following abstract:—

Diameter of the elementary fibres of striped muscle in fractions of an English inch.

Fish	$\frac{1}{755}$	$\frac{1}{65}$,	,, ...	$\frac{1}{222}$
Insects	$\frac{1}{753}$	$\frac{1}{200}$,	,, ...	$\frac{1}{419}$

I believe that the average diameter of the fibres in the human female is upwards of a fourth less than in the male, and that the average of both together is greater than that of other Mammalia; but a more extensive examination is requisite to establish this. Fish have fibres nearly four times thicker than those of Birds, which have the smallest of all animals. Next to Fish come Insects, then Reptiles, then Mammalia. In each of these different classes, however, an extensive range of bulk is observable, not only in the different genera, but in the same animal and the same muscle, some fibres being occasionally three, four, or more times the width of others. In general the fibres of the heart are smaller than those of other striped muscles. The varieties in the average bulk in different classes have a close connection with differences of nutrition and of their irritability, which will be reverted to.

3. *Figure.*—This is subject to some variety, depending on their number and manner of package. Sometimes, as in some parts of Insects, they are flattened; but when they are isolated, or loosely aggregated, they are more or less cylindrical. In all the cases, however, where many fibres are arranged side by side, as in the Vertebrata, the larger Insects, and Crustacea, they are irregularly polygonal, the contiguous sides being flattened, evidently from the effect of package. Yet some interspaces are always left for the passage of bloodvessels, nerves, and areolar tissue among and between them. Their form may be most readily displayed by a transverse section of a muscle that has been dried *en masse*, as long ago shown by Leeuwenhoeck (*fig.* 286).

4. *Colour.*—The colour of muscle depends partly on the colour of its elementary fibres, partly on the blood contained in its vessels, and there is strong reason to believe that the colouring matter of both is the same, or nearly so. That the fibres have always a colour of their own is at once evident on inspection under the microscope. It is generally more or less of a reddish-brown, but varies much in different animals and in different muscles, and even in the same muscle according to its state of development and activity. In Reptiles and Fish generally, and in Crustacea, the flesh is white, sometimes pinkish, but in some fishes, as the Gurnard, the gill-muscles are red. These varieties of colour are attended with none of structure. In Birds the colour varies much, being often white and deep red in the same animal, but generally the pectoral muscles are very dark.

b, b, sections of the injected capillaries, shewing the position they occupy among the fibres.

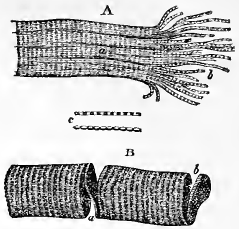
These figures shew th greater vascularity of the muscle with the narrower elementary fibres.

* Philosophical Transactions, 1840, p. 460.

The most deeply coloured muscle I have seen was the great pectoral muscle of the Teal (*Querquedula crecca*), killed after migration. In Mammalia the colour is ordinarily red, being deeper in the Carnivora than in the vegetable feeders. Among the domestic animals many varieties exist, which need not be specially enumerated. A considerable part of the colouring matter is extracted by repeated washing of a muscle, which then becomes pale, but not quite colourless; some part of the loss of colour here sustained is doubtless owing to the solution of the hæmatosine of the blood contained in it. A muscle, if hypertrophied, grows redder, and vice versâ; and probably the practice of bleeding calves some days before they are killed, makes their flesh more pale and tender, by causing the absorption of a portion of the proper colouring matter of the fibres, as well as by abstracting the blood circulating among them.

5. *Internal structure.*—Though the elementary fibres of all animals are visible to the naked eye, and in some animals, as the Skate (Raia Batus), are often as thick as a small pin, nothing of their internal organization can be distinguished without the aid of a powerful lens. There is indeed, in certain lights, a splendid pearly iridescence, resulting from the arrangement of their structure, and quite characteristic among the soft tissues; but this is not explained till a high power of the microscope is brought to bear upon the fibres. They are then seen, when viewed on the side, to be marked by innumerable alternate light and dark lines, whose delicacy and regularity nothing can surpass, and which take a parallel direction across them; and if the focus be altered so as to *penetrate* the fibre, they are found to be present within it just as on its surface, thus differing from those on the tracheæ of insects, which exist only at the surface. At the extreme border of the fibre the light lines are sometimes seen to project a trifling degree more than the dark ones, thus giving a slight scallop, or regular indentation, to the edge. If often happens, in tearing the fibres roughly with needles before examination, that they crack across, or give way entirely, along one or several of these dark lines, the line of fracture or cleavage running more or less completely through the fibre in a plane at right angles with its axis; and occasionally two or more of such complete cleavages will occur close together, the result of which is the separation of so many *plates* or *discs* (*fig.* 287, B), of which the light lines at the surface are the edges, and the corresponding light lines seen within are what may be termed the focal sections. Thus it is evident that there is a *tendency in the mass of the fibre to separate, when torn or pulled after death, along the transverse planes, of which the dark transverse stripes are the edges.* When such a separation takes place, a series of *discs* result, but to say that the fibre is a mere pile of discs is incorrect, for the discs are only formed by its disintegration. Nevertheless they are marked out, and their number and form are imprinted, in the very structure of the fibre, in its perfect state. (*Figs.* 287 and 288.)

Fig. 287.



Fragments of striped elementary fibres, shewing a cleavage in opposite directions, magnified 300 *diam.*

A, longitudinal cleavage.

At *a* the longitudinal and transverse lines are both seen. Some longitudinal lines are darker and wider than the rest, and are not continuous from end to end.

b, primitive fibrillæ, separated from one another by violence at the broken end of the fibre, and marked by transverse lines equal in width to those at *a*.

c represents two appearances commonly presented by the separated single fibrillæ. On the upper one the borders and transverse lines are all perfectly rectilinear, and the included spaces perfectly rectangular. In the lower the borders are scalloped, the spaces bead-like. When most distinct and definite, the fibrilla presents the former of these appearances.

B, transverse cleavage. The longitudinal lines are scarcely visible.

a, incomplete fracture following the opposite surfaces of a disc, which stretches across the interval and retains the two fragments in connexion. The edge and surface of this disc are seen to be minutely granular, the granules corresponding in size to the thickness of the disc and to the distance between the faint longitudinal lines.

b, another disc nearly detached.

But again, it always happens that *longitudinal* lines, more or less continuous and parallel, according to the integrity of the fibre and the strength and distinctness of the transverse lines, are also to be discerned; and like the transverse ones, not on the surface only, but throughout the whole of its interior. And it is found that there is a remarkable proneness in the fibre to split in the direction indicated by these lines also; by which splitting it is resolved into a great number of *fibrillæ*. These fibrillæ, like the discs, do not exist as such in the fibre, and to obtain them its structure must be necessarily broken up to a certain extent, for the union which naturally subsists between these parts must be destroyed. It is therefore most correct to say that there is an indication in the entire state of the fibre of *a longitudinal arrangement of its parts, occasioning a cleavage in that direction on the application of violence.* (*Fig.* 287.)

Sometimes the fibre will split into discs only, more often into fibrillæ only, but there are always present in it the transverse and the longitudinal lines which mark the two cleavages. It is the most common to find a crack or fracture taking both directions irregularly, running partly in the transverse dark lines, partly in the longitudinal dark lines, sometimes being crosswise on the exterior, more or less lengthwise within. These cracks are often short, even, well defined; at other times the parts near them are much stretched, or quite disorganized, — differences depending on the brittleness or toughness of the particular fibre, which qualities vary very much in different specimens, according to the state of nutrition, period of examination, and other circumstances.

Hence it is clear that the *discs* and *fibrillæ* consist of the same parts, and merely result from the different direction in which the mass breaks up. To detach a fibrilla entire is to remove a particle from every disc, and to take away a disc is to abstract a particle of every fibrilla. Thus, every disc consists of a particle of every fibrilla, and every fibrilla of a particle of every disc. Therefore every fibrilla of the same fibre has the same number of particles, and every disc in like manner is composed of the same number of particles.

If, now, isolated discs and fibrillæ be examined under a high magnifying power, they will be found to bear out, in the fullest manner, the description that has been given. The discs are marked on the edge by the fragments of the longitudinal lines, and if regarded on their flat surface, present a finely granular appearance, the granules being equal in diameter with the fibrillæ (*fig.* 288). In fact, the dark lines be-

Fig. 288.

Surface of a disc separated from an elementary fibre of a Lizard which had lain long in spirit. It displays the finely granular structure spoken of in the text. The granules are intended to be represented equal in size. Magnified 500 *diam.*

tween the granules are the fragments of the longitudinal lines of the interior of the fibre. Again, the fibrillæ, whether taken from the surface or from the interior, are always found to be marked at intervals by transverse dark lines, which are nothing more than the fragments of the transverse lines seen on and in the fibre. They uniformly correspond with them in distance and force (*fig.* 287, *c*). Thus, whether the fibre cleave crosswise or lengthwise, the resulting fragments bear in their structure their respective portions of the lines, taking an opposite course, and evincing a co-existent arrangement in the opposite direction; and when a detached disc or fibrilla is itself broken, the fracture follows the lines thus imprinted in its structure.

It remains to inquire, what is the nature and meaning of the dark lines so often mentioned?

They can be best examined in the separated discs or fibrillæ; and they appear to be undoubtedly the results of an unequal refraction of the light transmitted through the object. The light spaces intercepted between them, and which by their union constitute the discs and fibrillæ, have the aspect of small lenses or particles of higher refractive power than the connecting material, which consequently is in darkness when the inclosed spaces are in focus. By placing the object out of focus, however, the light and dark parts are reversed, which is precisely what occurs with true lenses. I have had a series of beaded rods of glass constructed, which have exactly the same appearance as the fibrillæ; and when two of these are regarded between the observer and the window, one being in front of the other, and their beads corresponding, the dark circumferences, visible round the beads of each rod when seen separately, are found to be converted into transverse bars, crossing the rods at right angles in the interval of the beads; or, in other words, forming the elements of the transverse stripes.

My friend, Dr. Gruby, of Vienna, informed me that he had had spiral rods of glass constructed, which, when placed in front of one another, have the same appearance as that often met with in the fibres, and he conceives the fibrillæ to be, consequently, spiral threads: an opinion advanced by Muys, to explain the phenomenon of contraction, but unnecessary for that purpose, and which is quite at variance with all I have observed on the subject. Such spiral rods, however apposed, can never present lines *absolutely* transverse, such as *always exist on the unmutilated fibre, and generally on the detached fibrillæ;* and the minute ziggags the stripes so often form, and which might, if constant, be possibly explained by the notion of spiral rods, are the mere result of a stretching and disturbance of the direction of the axes of the particles composing the discs and fibrillæ. But the cleavage of the fibre into discs is especially opposed to the idea of a spiral form of each fibrilla.

I think it is clear that the dark lines in both directions are not occasioned by a difference of colour, but solely by a variety in refraction; but on what this difference in refraction depends it is more difficult to explain. Is the connecting material of a different refractive power, or of the same nature as the particles it unites? If of the same nature, it must be of smaller dimensions, and minute interspaces must be left; but of the existence of such interspaces there is no conclusive evidence. It seems more probable that the connecting material is less dense, and fills up every interval; but I do not pretend to determine what may be its nature, or whether it differs chemically from the parts it serves to join.

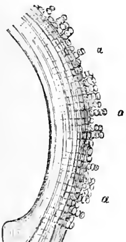
It is remarkable that the direction of the cleavage should vary so much in different specimens, without it being possible to say on what the variety depends: and the question has still to be determined, whether the transverse and longitudinal modes of union between the particles are the same. It is most likely that they are, and the differences in the regularity and breadth of the transverse and longitudinal lines are easily explained on that supposition.

The transverse dark intervals between the particles, being all ranged on the same plane, the edge of which is directed to the observer, when he looks on the side of a fibre, appear as a sharp line, while the longitudinal dark intervals not being on a plane, are seen irregularly one in front of the other, as a little consideration will shew. Hence the latter seldom seem so definite or regular as the former. Nevertheless their union, seen on the surface of a detached disc, often presents much regularity, and forms curved or straight lines, such as result when a number of balls of equal size are huddled together on a level.

It may be concluded from what has now been advanced, that the discs and fibrillæ, (or, in other words, the general mass of the fibre,) are made up of a number of particles, which I have termed *primitive particles*, or *sarcous elements*, and which would be obtained in a detached form by a general separation occurring along the transverse and longitudinal lines visible in the fibre. The existence of these particles, as well as their form and size, is indicated in the structure of the fibre, while yet entire; but they are united together, and have no independent existence, each being by its very nature a part of the mass, which is rendered incomplete by the removal of a single element. It results also from this description that these particles have no definite outline on all their aspects, being united together; and that they only obtain such an outline on being severed; on which account it is perhaps impossible to say whether, *in the perfect fibre*, they be rounded, square, or polygonal.

An example of the strong lateral union of these particles to one another was presented by the specimen from which the following sketch was taken. It consisted of two or three elementary fibres from the leg of a newly-born rabbit, which had been kept for some months in weak spirit. They were lying in a curved form on the field of the microscope, and presented on the convex edge transverse series of the particles, which, having lost their longitudinal while they retained their lateral union, stood out in relief, as represented in *fig*. 289, *a*, *a*, *a*.

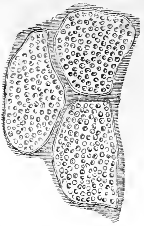
Fig. 289.



In the intervals between the projecting particles, others have become detached.

It sometimes happens that a linear series of them (a fibrilla) is separated, which has the appearance of a necklace of beads, with constricted intervals, while at other times the intervals, though dark, are of equal width with the light or highly refracting particles. Again, it is possible, by steeping in acid a transverse section of a dried muscle, to separate the particles considerably from one another, and to see that they are granules acting as lenses, being much more refractive than the material connecting them. Such transverse sections are an artificial division into discs, and the intervals between the particles widen out most in specimens taken from birds (*fig*. 290).

Fig. 290.



Transverse section of three elementary fibres of the dried pectoral muscle of the Teal, (Querquedula crecca,) treated with weak citric acid, shewing the round refracting particles separated from one another. The cut edge of the tubular sheath of each fibre is also seen.

It is in these *sarcous elements* that the contractile power resides, and, as they are apt to retain after death the varying effects of the contraction they have undergone during the rigor mortis, it is not easy to give an exact measurement of their size or shape. An average drawn from very numerous observations shews, however, that they are very nearly alike in these respects in all animals and at all periods of life. Their diameter in the longitudinal direction of the fibre, as indicated by the distance between the transverse lines, is thus shown to be:*

	Eng. Inch.		No. of Observations.
In the Human subject. .	$\frac{1}{9400}$	..	27
In Mammalia generally	$\frac{1}{10900}$	..	15
In Birds.	$\frac{1}{10400}$	..	7
In Reptiles	$\frac{1}{11500}$	..	7
In Fish.	$\frac{1}{11100}$	..	20
In Insects	$\frac{1}{9500}$	..	8

Their diameter in the opposite direction or that marked by the distance between the longitudinal lines is less, often by a half, but liable to variety from the cause already specified.

In a paper, entitled "On Fibre," read before the Royal Society, on the 16th December and the 6th January last,† Dr. Barry describes the *fibrilla* to be a *flat filament* rounded at the edges, and deeply grooved along the middle line on both its surfaces. He states that this *flat filament* consists of *two spiral threads* placed side by side, *with their coils interlacing*: that it "is so situated in the fasciculus (elementary fibre) of voluntary muscle, as to present its edge to the observer;" and that the curves of the spiral thread, then seen, seem to have been the appearance that "suggested the idea of longitudinal bead-like enlargements producing the striæ." In Dr. Barry's opinion "the dark longitudinal striæ are spaces (probably occupied by a lubricating fluid) between the edges of flat filaments, and the dark transverse striæ, rows of spaces between the curves of the spiral threads," of which each flat filament consists. "In a postscript, the author observes, that there are states of voluntary muscle in which the" (doubly-spiral, flat,) "longitudinal filaments have no concern in the production of the transverse striæ, these striæ being occasioned by the windings of spirals, within which very minute bundles of longi-

* Auct. loc cit. p. 474.
† Proceedings of the Royal Society, No. 51.

tudinal" (doubly-spiral, flat,) "filaments are contained and have their origin."

This description, so entirely opposed to the more simple view above given (and which was already in type when the paper "On Fibre" was read) demands a brief notice. The paper of which it forms part, might perhaps have been more explicitly entitled, "On the double spiral structure of the organic world;" for, in it, the doubly-spiral flat filament, giving the appearance of transverse striæ to voluntary muscle, is discovered to exist in the interior of the blood-corpuscles of all animals, and "apparently in every tissue in the body. The author enumerates a great variety of organs in which he has observed the same kind of filaments." "And if the author's view of identity in structure between the larger and the smaller filaments be correct, it follows that spirals are much more general in plants themselves than has been hitherto supposed; spirals would thus appear, in fact, to be as universal as a fibrous structure." "Valentin had previously stated, that in plants all secondary deposits take place in spiral lines. In the internal structure of animals, spirals have heretofore seemed to be wanting, or very nearly so. Should the facts recorded in this memoir, however, be established by the researches of other investigators, the author thinks the question in future may perhaps be, where is the 'secondary deposit' in animal structure, which is not connected with the spiral form? The spiral in animals, as he conceives he has shown, is in strictness not a secondary formation, but the most primary of all; and the question now is, whether it is not precisely so in plants."

As these speculations profess to be grounded solely on observations of particular structures, of which muscle is one, I shall make no apology for applying my few remarks solely to the account of this structure, which is all that can properly be considered here. A renewed examination of this tissue has confirmed, fully and decisively to my own mind, the account I gave of it in 1840, and which was the result of two years' study. 1. I find that when the natural and ready cleavage happens to be into fibrillæ (and I do not pretend to explain why this cleavage should be at one time into fibrillæ and at another time into discs, I only know the fact,) these solitary and isolated fibrillæ do not present any such central longitudinal groove, as Dr. Barry describes, to indicate their double nature: that the cross lines are usually *transverse*, and *not oblique*, by which I mean that the spaces they bound have a *rectangular outline*, so sharp and definite, that the mind rests entirely satisfied that there cannot be two opinions concerning them, between any who have examined the object in one of Powell's *best microscopes*, and with the use of that admirable definer and clarifier of the image, the *achromatic condenser*. That *right angles* can be produced by a *spiral*, whether *double* or *single*, however distorted by accident or violence, it is impossible to conceive. That these transverse lines may sometimes become oblique by irregular traction, such as is almost necessarily applied in preparing the object, is most easy to understand, if we bear in mind, that the substance in the different spaces which they circumscribe is one united mass. 2. The transverse cleavage of the elementary fibre, which I first showed to be occasionally so complete as to separate it into discs, cannot be reconciled with Dr. Barry's statement. For the surfaces of such discs present, as in *fig.* 288, a fine granular aspect, and *no ends of doubly spiral threads.* And the definite and beautiful appearance presented by a transverse section of the fibre in all animals, but especially in Birds (*fig.* 290), is totally at variance with his views: for the particles there displayed are *highly refracting*, *round*, and *not aggregated in pairs.* The condition represented in *fig.* 289 is not less opposed to them. Other proofs might be adduced, but they would lead to greater detail than is compatible with the form of the present publication; and perhaps they will be allowed to be unnecessary.

6. *Of the corpuscles of the elementary fibre.* The elementary fibres always contain, among their primitive particles, a number of *corpuscles*, which either are, or are analogous to, the nuclei of the cells of development, of which this and other structures have originally consisted. These corpuscles are visible in the early stages of growth (*fig.* 291), but disappear towards the close of fœtal life, as the lines resulting from the deposit of the contractile particles

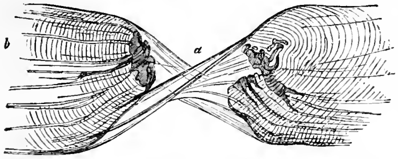
grow dark. The addition of a little acid, however, swells the fibre, obliterates the cross lines, and brings the corpuscles into view, not only at this early period, but at every subsequent one, even to old age. In insects, the nuclei in the earliest stage are a single or double series in the axis of the fibre, and in the perfect fibre they hold the same position (*figs.* 292 and 293, *c*). In the Vertebrate classes they have a like correspondence, being scattered equally throughout the mass, in both fœtal and adult states. Where the fibre is small, however, they usually abound more towards the surface. They are oval and flat, and of so little substance, that though many times larger than the primitive particles, and lying amongst them, they do not interfere with their mutual apposition and union. These corpuscles are frequently the cause of irregular dark longitudinal streaks, seen in the fibre by transmitted light. They usually contain some central granules or nucleoli (*fig.* 295). It is doubtful whether the corpuscles or nuclei originally present remain through life, or whether successive crops advance and decay during the progress of growth and nutrition. But it is certain, that, as development proceeds, fresh corpuscles are deposited, since their absolute number is far greater in the adult than in the fœtus, while their number, relatively to the bulk of the fibre, at these two epochs, remains nearly the same.

7. *Of the sarcolemma, or tunic of the elementary fibre.*—This is a simple transparent homogeneous membrane of extreme tenuity, but very tough and elastic, which, in the form of a perfect tube, invests every elementary fibre, adheres to its surface, and isolates it from surrounding parts. It is universally present in voluntary muscles, and may be demonstrated in a variety of ways. When the fibres have been immersed in alcohol, which causes them to shrink, it is often seen wrinkled on their surface; or when they are cracked or broken across, it frequently remains entire and connects the severed fragments (*fig.* 294). This method of showing

Fig. 294.



Fragments of an elementary fibre of the Skate, held together by the untorn but twisted sarcolemma.
a, Sarcolemma. *b, b*, opposite fragments of the fibre.

it is best followed in the case of the large and brittle fibres of the Skate; or, it may be seen cut across in a general transverse section of a dried muscle (*fig.* 290). When the texture of the fibre is destroyed by maceration, the broken mass is sometimes retained by the sheath, which thus becomes visible. When the fibre swells by acid, this tunic resists, and the swollen mass emerges at its broken and open end: but, if this is not effected with sufficient celerity, the sarcolemma may give way at different points, being burst by the mass, which thus forms herniæ. Such protruding masses being unequally stretched have their transverse and longitudinal lines distorted from their true direction and thrown into very elegant curves (*fig.* 295). Again, if a fibre still

Corpuscles are seen scattered throughout the mass, and some detached ones, d, are represented below. Their average diameter is one-thousandth of an English inch.

retaining its irritability, be immersed in water, this fluid, on being absorbed, excites contraction, by which it is immediately expelled from among the primitive particles. When thus forced out it usually collects between the fibre and its sheath, raising the latter in the form of bullæ (*figs.* 301 and 302, and Art. MUSCULAR MOTION). The progress of this interesting phenomenon evinces the adhesion that exists between the fibre and its sheath. The bullæ immediately subside, by the transudation of their fluid, when the part is placed in thick syrup. I once met with a singular demonstration of the existence and properties of the sarcolemma, in finding it filled with numerous *trichinæ* (*fig.* 296), which had taken the place of the contractile material, the sheath preserving all its characteristic beauty and transparency.*

I discovered this remarkable membrane in Insects, Crustacea, and all the tribes of Vertebrata, in 1839, not knowing that Professor Schwann had previously described it in connection with the development of muscle in Insects and Fish.† He believes it to be a persistent portion of the membrane of the original cells of de-

velopment, united to form a single tube, the septa at first resulting from their apposition having been absorbed. This opinion is undoubtedly ingenious; but, as I have yet no data from which to judge of its correctness, I neither admit nor deny it. I have seen the sarcolemma in human muscle as early as the period of birth, and have traced it at all epochs, to old age, when the atrophy of its contents has often seemed to render it more easy of detection. It also remains in muscles wasted by disease or accident at other periods of life, and no difference appears to occur in it whether the specimens examined are pale or dark-coloured, firm or flaccid. It is thickest in those classes that possess the thickest elementary fibres, viz. in Crustacea and Fish, and so thin in Birds, whose fibres are the smallest, that it is often difficult to detect it at all.

With regard to the *use* which this singular structure may serve in the economy of the organ, our present ignorance of the manner in which motion is excited renders any explanation that might be offered of doubtful value. But it has appeared probable to me, first, that it may act as a mechanical protector and isolator of the contractile tissue enclosed within it; secondly, that its exquisitely smooth external surface may facilitate those rapid minute motions of neighbouring fibres, one against another, which may be shown to occur in contracting muscle (see MUSCULAR MOTION); and, thirdly, that from its apparent similarity in structure to the membrane of the nervous tubules, which run among the fibres, and between which and the proper contractile tissue it seems certainly to intervene, as well as from its extensive contact and union with the surface of the contractile tissue, it may be the conducting medium of that influence, whose mode of propagation the late discovery of the loop-like termination of the nerves in muscle has hitherto only seemed to render more inexplicable than ever.

8. *Of the extremities of the elementary fibres, and their attachment to other structures.*—Every fibre is fixed to fibrous tissue, or to something analogous to it; but an accurate examination of this difficult subject gives no countenance to the ordinarily received opinion that this tissue is prolonged over the whole fibre from end to end, as its cellular sheath; nor is this view reconcileable with the physical requirements of the case. After many trials I have never succeeded in isolating a muscular fibre with the tendinous fibrillæ pertaining to it, in either Mammalia or Birds; but this may be occasionally accomplished in Fishes, and in certain muscles of insects. In these examples the minute detachment of the fibrous tissue may be seen to pass and become attached to the truncated extremity of the fibre. The fibre ends by a perfect disc, and with the whole surface of this disc the tendon is connected and continuous (*fig.* 297). The sarcolemma

Fig. 297.

a, a, line of union between the two structures.
b, tendon.
c, muscle.

ceases abruptly at the circumference of the terminal disc, and here some small part of the tendinous material appears to be joined to it. The same disposition may be well seen in the legs of certain insects (*fig.* 293). In other cases, where the muscle is fixed obliquely to a membranous surface, each fibre is obliquely truncated at its extremity, at an angle determined by the inclination of its axis, instances of which may be seen in the limbs of Crustacea, and elsewhere.

9. *Development.*—The researches of Valentin and Schwann have shewn that a muscle consists in the earliest stage of a mass of nucleated cells, which first arrange themselves in a linear series, with more or less regularity, and then unite to constitute the elementary fibres. As this process of agglutination of the cells is going forward, a deposit of contractile material gradually takes place within them, commencing on the inner surface and advancing towards the centre, till the whole is solidified. The deposition occurs in granules, which, as they come into view, are seen to be disposed in the utmost order, according to the two directions already so often mentioned. These granules are the *sarcous elements*, and being of the same size as in the perfect muscle, the transverse stripes resulting from their apposition are of the same width as in the adult; but as they are very few in number, the fibres which they compose are of corresponding tenuity. From the very first period of their formation these granules are parts of a mass and not independent of one another, for as soon as solid matter is deposited in the cells, faint

indications of a regular arrangement in granules are usually to be met with. It is common for the longitudinal lines to become well-defined before the transverse ones. When both are strongly marked, as is always the case at birth, the nuclei of the cells, which were before visible, disappear, being shrouded from view by the dark shadows caused by the multitudinous refractions of the light transmitted through the mass of granules; but, as before stated, they can still be shown to exist by immersion in a weak acid, which, while it swells the fibrinous material of the granules and obliterates their intervening lines, has no action upon the nuclei.

b. Of the unstriped elementary fibres.—This variety possesses far less interest than the other in consequence of its apparent simplicity of structure. The fibres consist of flattened bands, generally of a pale colour, bulged at frequent intervals by elongated corpuscles similar to those of striped muscle, and capable of being displayed by the same process (*fig.* 298). The texture of these fibres seems to be homogeneous. By transmitted light they have usually a soft, very finely mottled aspect, and without a darkly-shaded border. Sometimes the mottling is so decided as to appear granular, and occasionally these granules are arranged in a linear series for some distance. This condition is probably an approximation towards the structure of the striped fibre, for I have observed the granules to be about the size of the sarcous elements already described. It is generally to be seen more or less distinctly in the gizzard of Birds, and I have now and then met with it in the fresh muscle of the stomach, intestinal canal, urinary bladder, and uterus of Mammalia. The ordinary diameter of the unstriped

a, treated with acetic acid, and shewing the corpuscles.
b, fragment of a detached fibre, not touched with acid.

fibre is from $\frac{1}{2000}$th to $\frac{1}{3000}$th of an inch. From this account of the appearance of these fibres, it might be expected that their discrimination from other tissues would be often difficult. And, in fact, it is so to an inexperienced eye. The peculiar texture, however, the size, the soft margin, and, above all, the presence of *numerous* elongated oval corpuscles, with two or three granules in their centre, are characters which, taken together, I believe to be decisive. As a number of fibres usually take a parallel course together, the bulgings occasioned by the corpuscles give rise to partial longitudinal shadows, extending for some way beyond the corpuscles, in the intervals of the fibres. As these irregular longitudinal shadows occur pretty uniformly throughout an aggregation of fibres, and as some are necessarily out of focus, while others are in focus, the whole mass commonly presents a very confused reticulate appearance, which has given rise to an almost universal notion that these fibres do, in reality, interlace one with another, and do not run parallel. This notion, however, is, in most cases, erroneous. It is doubtful whether these fibres are invested in a sarcolemma: none has hitherto been detected in an unequivocal manner. It is also still a matter of speculation how they terminate, or whether they in all instances have a termination. In the case of the more or less circular set of fibres, inclosing the small intestine, for example, it is uncertain whether each fibre surrounds the canal once, returning into itself as a ring, or, more than once, as a spiral, or whether it passes only partially round it, the rest of the circle being completed by others. Whether the areolar tissue (the representative of the fibrous) that is always found in connection with these fibres, serves to give them an attachment by union with their extremities, or by involving them in its meshes, is also altogether unknown. In the gizzard of Birds the ends of the fibres are united to white fibrous tissue, thus making an approximation to the striped fibre, as they do in colour. But I have not been able, after diligent search, to detect the true transverse stripes, which Ficinus describes to exist in this organ.

Of the mode of aggregation of the elementary fibres.—The two kinds of fibre whose structure has now been described, are aggregated into masses of very various shape and bulk, and supplied with areolar tissue, vessels and nerves, so as together to form the organs termed muscles. But if we trace these organs downwards through the animal scale, we come to examples in which solitary fibres exist without any such appendages, and yet evidently performing the office of, and truly constituting, a perfect muscle. And even many fibres are found, so far smaller than the usual dimensions as to consist of only one or two linear series of sarcous elements, and these perhaps only visibly present near the centre of the fibre, where developement is most advanced, and the contractile energy greatest. In such minute and simple forms we may perceive a transition from the striped towards the unstriped fibre, the transverse lines being often irregular, broken, or faintly marked. And we may also discern a clue to the meaning of the structural condition which is found in the complicated muscles of the higher animals. The essential contractile material is the fibre, and its mass is accurately proportioned to the power demanded. If this is below that of a single elementary fibre, the fibre is reduced in proportion; if more is required than one fibre can supply, the size of this is not increased but its number multiplied. The point at which an increase in number supersedes one in size, is that which has been already stated to be the average bulk of the fibre. This differs in the different classes of animals, and corresponds with the demand there may be in each class for vascular and nervous supply. For by the very constitution of the contractile materal, it can receive neither vessels nor nerves into its interior substance, and therefore it must be itself subdivided further and further in proportion to the amount of these which are to be in contact with its surface.

In the compound organs termed muscles, the fibres are usually disposed in parallel sets of 10, 20, 30, or more, surrounded and held together by a delicate areolar tissue, which penetrates more or less among the individual fibres, but does not necessarily invest each one of them from end to end, as it is frequently described to do. Where the fibres are not very large, it is often difficult to discern any areolar tissue at all in connexion with them. These first sets admit of considerable motion on one another, in consequence of the looseness of their areolar sheath. Like the elementary fibres themselves their figure is polygonal, for they in their turn are arranged (if the muscle be large enough) into secondary sets, and are flattened by being pressed together. These again are aggregated into tertiary sets, and these into still larger ones, according to the size of the particular organ. All these sets partake of the polygonal figure of the elementary fibres; except the portion that forms a part of the general exterior of the muscle, which is usually more or less rounded. As the packets of fibres are larger, so their angles are more rounded, and their surface covered with a more abundant areolar sheath, and they approach, in fact, to the condition of a perfect muscle, which is itself included in an envelope of areolar tissue. Their angles are thus rounded in consequence of the greater quantity of areolar tissue, and of the larger size of the vessels and nerves that occupy their intervals. For the same reason the elementary fibres themselves are less sharply angular, when very small, as in Birds, because the vessels accompanying them are proportionally more abundant, and occupy more space in their intervals.

The arrangement of the elementary fibres into these packets has received more attention than its importance deserves, and anatomists have endeavoured to affix definite names (fasciculi, lacerti, &c.) to certain sizes of them. But no division of this kind is to be found in nature. It may be safely said that packets of every possible bulk exist from the simple set of two or three fibres, to those of many thousands, these last being subdivided with the greatest irregularity. And it is only in muscles possessed of some thickness that any such package in sets is to be met with. The abdominal plane muscles, which contain such an arrangement in the larger animals, are, in the smallest, composed of a single unbroken layer of elementary fibres. A similar diversity exists between muscles of different size and shape in the same animal. In the gluteus maximus, which is liable to pressure and change of position from its peculiar situation, the fibres are made up into lacerti, about one-quarter of an inch thick, surrounded with a dense areolar sheath, and attached loosely to one another; while the glutei situated underneath are, like the psoas, unprovided with such dense septa of areolar tissue, and seem more uniform throughout.

From these and many other considerations which might be adduced, it may be clearly seen that the mere aggregation of the elementary fibres in a muscle into larger or smaller sets, is determined solely by its own peculiar circumstances and exigencies, and is not of a nature to demand particular description in so general an account as the present.

The direction of the elementary fibres of voluntary muscles is usually straight, between their points of attachment, which are always some form of the fibrous tissue. This tissue may be so arranged as that the sets of muscular fibres passing from it, may be either parallel or oblique to one another, but the fibres forming any one set are generally placed in a parallel series. If the fibrous tissue form a laminar expansion on the surface of a muscle, the muscular fibres pass off from it obliquely, either to a similar expansion on the opposite surface or to a tendon. If they arise from an extensive surface of bone (i. e. of periosteum) they conduct themselves in a similar fashion, and also if they pass from a line of tendon or of bone. In all these cases the muscle may be styled penniform. If a thread or sheet of fibrous tissue dip into the interior of a muscle, it gives origin to the muscular fibres on both sides, and they diverge from it obliquely: such a muscle is styled doubly penniform. When several such sheets enter the muscle at both extremities, and give attachment to the fibres obliquely placed in the intervals, the muscle is styled compound penniform, as the deltoid.

One result of the varied arrangement of the tendinous fibres with regard to the muscular, is the production of symmetry and beauty of form; a second is convenient package; a third is the adaptation of the particular muscle to the kind and amount of exercise which is required of it. Where a great mass of fibrous tissue runs into a muscle, the number of fibres and their obliquity is very much increased, while the length of each is diminished; and, as a general result, the power of such a muscle is augmented, while the extent of its contractions is limited. The same mass of contractile material may be arranged as a few long fibres (as in the sartorius), or as many short ones (as in the masseter). In the former case its contractions would be characterized by their extent, in the latter by their power; for, *cæteris paribus*, the extent is as the length, the power as the thickness.

The terms *origin* and *insertion* are employed with great convenience in ordinary anatomical language to denote the more fixed and the more moveable attachments of muscles. In human anatomy general consent has sanctioned their use, and even, with few exceptions, their particular application to each muscle in the body, although this assignment is in many cases arbitrary, in consequence of its being impossible to determine which attachment is the more frequently the fixed one.

The arrangement of the fibres in the heart has been already fully treated of in this work. (See Heart, Fibres of.)

In the muscular coat of the alimentary canal, of the bladder, and uterus, the unstriped fibres are disposed, as in the heart, so as to enclose a cavity, but without having, as in that organ, any point at which they can be said to commence or terminate. In the alimentary tube they are arranged in two laminæ, the respective fibres of which take a course at right angles to each other. In the bladder the arrangement is reticulate. The elementary fibres form sets of variable thickness, which at numerous points send off detachments to join neighbouring bundles, whence has sprung the notion that the fibres are branched. It is manifestly, however, the sets of them only that are branched, the unstriped like the striped fibres being invariably simple from end to end. In the uterus the disposition of the fibres is essentially similar, calculated to allow of great variety in the capacity of the cavity they encircle.

Of the areolar tissue of muscles.—This tissue is much more abundant in the voluntary than in the involuntary muscles. In the former it forms an external investment, which sends septa into the intervals between the larger and smaller packets of fibres, and thus enables them to move in some degree independently of one another. The *density* of these general and partial sheaths is proportioned to the amount of pressure to which the organ may be subject, as is exemplified in the superficial muscles of their back, and in those superficial muscles generally where a fibrous aponeurosis does not perform the same office. The areolar tissue does not usually clothe every individual fibre from end to end, giving it a cellular sheath, except in cases where the elementary fibres are of large dimensions. Besides the protection the areolar tissue affords to the muscular fibres, it admits of motions between them. But it must also serve the important office of limiting undue motions of one part of a muscle on another part, by its forming a connecting bond between neighbouring bundles. But a principal use of it appears to be that of furnishing a resisting nidus in which the delicate vessels and nerves can traverse the interstices of the fibres, and by which they can be protected from hurtful dragging during the unequal and oscillating movements of the fibres of a voluntary muscle during its state of activity. This idea is supported by the fact that scarcely any areolar tissue exists in the heart or in the unstriped muscles generally. In the heart, though the contraction is powerful, it is instantaneous or nearly so, and therefore probably more uniformly diffused, so that neighbouring fibres must be less moved on one another than in the more sustained contraction of a voluntary muscle. Moreover the mutual intertwining of even the elementary fibres in this organ is, in many parts of it, so intricate, as to contribute much to their mutual support. And in the other involuntary muscles, the contractions are slowly and evenly progressive along the fibres of the same set.

Of the bloodvessels of muscles.—The arteries and veins of muscles commonly run together, and most of the arterial branches, to within two removes from the capillaries, are accompanied by two *venæ comites*. They invariably pass more or less across the direction of the fibres, divide and subdivide, first in the intervals between the larger sets, then between the smaller sets, till the ultimate twigs insinuate themselves between the fibres composing the smallest bundles, and break up into their capillary terminations. In this course the vessels supply the areolar tissue, their own coats, and the attendant nerves. The capillary plexus of the areolar membrane consists of irregular but pretty equal-sized meshes, and contrasts strongly with that of the muscular tissue itself. The *proper capillaries* of muscle are quite characteristic in their arrangement, so that a person who has once seen them can never afterwards mistake them. They consist of longitudinal and transverse vessels, the longitudinal always following the course of the elementary fibres, and lying in the intervals between them, the transverse being short communications placed at nearly equal distances between the longitudinal ones, and crossing nearly or quite transversely over or under the fibres. The manner in which the longitudinal vessels are placed in relation to the fibres, is seen in *fig.* 286, where I have represented them as they are seen on a transverse section. They usually occupy the interstice between three or more fibres, but sometimes also the space between the contiguous surfaces of two fibres. The length of the longitudinal vessels does not usually exceed the twentieth of an inch; in other words the terminal twigs of the artery and vein pertaining to the same capillary are seldom further than that apart. The length of the transverse anastomosing capillaries necessarily varies with the thickness of the fibres over which they pass (*fig.* 299). The diameter of the capillaries of muscle varies like that of others with the size of the blood-particles of the animal. It is, however, only just sufficient to allow of the particles to pass. If a fragment of a frog's muscle, perfectly fresh, be examined, series of blood-particles will be seen in the longitudinal capillaries. These

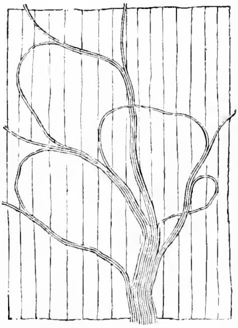
e, an elementary fibre, to show the relative size and direction of those to which the capillaries here represented are distributed.

particles are compressed and elongated, sometimes to a great extent, evidently by the narrowness of the canal which contains them. It may seem at first sight not doubtful that in the living creature these elastic blood-discs are similarly elongated in their passage through the vessels of muscle, but the admirable researches of Poiseuille will perhaps serve to explain this appearance without our being driven to suppose the presence of so formidable an obstacle to the capillary circulation through these organs. It is more probable that the contraction of the vessels and the compression of the blood-discs occur, on some of the contents of the vessels being permitted to escape by the severing of the fragment for microscopic examination. The coats of the capillaries of muscle consist of a simple diaphanous membrane, in which a few irregular-shaped cytoblasts occur at infrequent intervals.

Of the nerves of muscle.—The distribution of the nerves through muscular structures has always been a subject of great interest with those who looked to this line of inquiry for some clue to the explanation, either of that wonderful active connexion subsisting between them, or of the nature of the contractile act itself. But though the anatomical results accruing from this inquiry are of a highly satisfactory kind, considered in themselves alone, yet they cannot be said to have hitherto contributed, in any great degree, to the elucidation of these mysterious questions. The best mode of inspecting the arrangement of the ultimate nervous twigs, is to select a very thin muscle, (as one of the abdominal muscles of any small animal, or one of the muscles of the eye of a small bird,) to steep it in weak acetic acid, and then thin it out under the compressorium. The primitive tubules of the nerve may then be readily distinguished with a power of 100 to 200 linear. They separate from one another, at first in sets, afterwards in twos, threes, or fours, and if these be followed they will be found ultimately separating from one another, forming arches, and returning either to the same bundle from which they set out or to some neighbouring one (*fig.* 300). In this loop-like course they accompany to some extent the minute bloodvessels, but do not accurately follow them in their last windings, since their distribution is in a different figure. They pass among the fibres of the muscle, and touch the sarcolemma as they pass; but as far as present researches have informed us, they are entirely precluded by this structure from all contact with the contractile material, and from all immediate intercourse with it. How then shall we explain the transmission of the nervous influence to a material thus enclosed? If it were wise or safe to go a single step in advance of pure observation on so abstruse a question, we might suggest, resting on the seemingly sure ground of exact anatomy, that this influence must be of a nature capable of emanating beyond the limits of the organ which furnishes it. But further than this, as to how, or to what extent this influence may so emanate,

Fig. 300.



Loop-like termination of the nerves in voluntary muscle. After Burdach.

or as to what may be its nature, it would, perhaps, in the present state of knowledge, be hardly warrantable even to speculate.

d. Of the distribution of the striped and unstriped fibre in the body.—The striped fibre is met with in all the voluntary muscles, and in a few involuntary, as the constrictors of the pharynx and the muscular coat of the œsophagus, and the heart. In the œsophagus it appears to be mingled with the other variety to a somewhat uncertain extent. In some specimens from the human subject I have been unable to detect any striped fibres in the lower half of that tube, either in the circular or longitudinal layer, but in other examples they have been traceable to within an inch of the stomach. Among the lower animals considerable differences occur, as has been well pointed out by Mr. Gulliver,* who observes that in general " the muscular fibre of animal life (striped) extended further towards the stomach in the outer than in the inner layer of the œsophageal muscular sheath." In several animals this gentleman found the striped fibres even on the stomach (as in the Rabbit, *Lepus cuniculus*, Linn., the Sheep, *Ovis aries*, Desm., the Sloth Bear, *Ursus labiatus*, Blainv.) while in many others he met with them to within a very short distance of that cavity. Dr. Todd has also shewn them to me on the glandular pouch at the cardiac extremity of the stomach in the Dormouse. It is still unknown in what manner the two varieties of fibre are arranged at this point of junction, some supposing that they are simply intermixed, others that they pass into one another by imperceptible gradations. The former of these views is that which appears most consonant with my own observations. Mr. Skey considers † that the fibres of the heart " possess a somewhat compound character of texture," and this opinion seems highly probable. They possess, it is true, the transverse stripes indicative of an arrangement of particles in parallel series, but there is frequently a want of that uniformity and precision in this appearance which so remarkably characterize voluntary muscle. The cross lines are apt to be broken and interrupted, and are sometimes difficult to discover at all. This condition is well represented by Mr. Skey in fig. 5 of his second plate. In some of the smaller and lower animals the particles never form transverse stripes. These fibres, as explained by him, are smaller than the average diameter of the voluntary muscles of the same subject by two-thirds, and in most parts of the heart they are not aggregated in parallel sets, but twine and change their relative position. Striped fibres have been found in the iris, in the small muscles of the ear, and in those muscular fasciculi that surround the urethra immediately in front of the prostate. They are also found in the sphincters of the anus and vagina.

The unstriped fibre is met with in the alimentary canal from the middle of the œsophagus to the rectum, and constitutes the double layer investing that tube. It also forms the muscular coat of the bladder and that of the uterus. The dartos owes its contractility to the presence of fibres of this variety, which, in consequence of the abundant admixture of areolar tissue, has not hitherto been clearly recognized; but it may be detected by the addition of acetic acid, which, by bringing into view the peculiar corpuscles it contains, distinguishes it from both the white and yellow fibrous elements of the areolar tissue. But even without this chemical test, to which some may object, it is possible to discover this form of muscular fibre in the dartos, by the characteristic appearances which have been already attributed to it. Since satisfying myself of the real existence of this fibre in the dartos, I have on many occasions detected a very decisive peristaltic action advancing from one side of the scrotum to the other, and continued for a considerable period, yet of a kind which it was impossible to refer, with any degree of probability, to the cremaster. In one case particularly, occurring in the practice of Mr. Fergusson, where the tunica dartos was much hypertrophied, in connection with an old stricture of the urethra, we observed this peristaltic contraction of a very vigorous description. The fibres which have been described as peculiar to the dartos seem to be nothing more than a certain modification of the areolar tissue in that region. In the corpora cavernosa penis of the horse there is a large quantity of this kind of fibre, as may be ascertained by microscopic examination, although Professor Müller* seems indisposed to consider it really muscular. He states that " viewed in the microscope these fibres do not present any resemblance to muscular fibres," but my own examinations of them have not confirmed this statement. They appear to me to have all the characteristics of this variety, and by acetic acid are seen to contain a great number of corpuscles. Moreover they appear to consist chemically of fibrine. Professor Müller has failed in exciting contraction in them in the living horse, but this is not a conclusive fact as to their nature, for it may be and probably is the case that they do not act unless stretched by the erection of the organ. In the quiescent condition of the part they may be considered to be in a contracted state, like the muscular coat of an empty intestine, and so would naturally appear to be unaffected by the stimulus of galvanism. The erection of the penis seems with great probability to be attributable to pressure exercised on the superficial veins of the organ by a continuation of a structure analogous to the dartos, and certainly containing the unstriped muscle, which is continued over the base of the penis under the skin. The erection of the nipple also occurs, on any mechanical irritation, with a motion so very much resembling the peristaltic action of muscular fibres, that I have little doubt such would be found, constituting a layer, under the skin in that region. And it may be matter of inquiry how far the general contractility of the skin is dependent on a diffusion of this tissue, in small quantities, throughout its areolar structure. The excretory ducts of all the larger glands appear to possess a covering of fibre belonging to this

* Proceedings of the Zoological Society of London, No. 81, Sept. 1839.

† Phil. Transactions, 1837, p. 381.

* Physiology, by Baly, second edition, p. 250.

variety. Such is the case with the ductus choledochus in Birds, and probably in Mammals, and in the ureters and vasa deferentia. The bronchial tubes may be mentioned under this head as the best marked example of this arrangement. The trachealis muscle consists evidently and entirely of the unstriped fibres, and the same may be traced down the bronchial ramifications as far as the air-cells themselves, though not into them. The distinctive characters of this form of muscle may here be unequivocally discerned, and if anatomists had been better acquainted with them, there would not have been room for those disputes regarding the muscularity of the bronchial tubes which have so long attracted the interest of practical physicians. Recently, indeed, there has been added to the satisfactory evidence of anatomy the well proved fact that these fibres may be excited to contraction by the galvanic stimulus.* In the case of other glands it is still unknown how far the muscular coat invests the ramifications of the duct; it is most likely that it gradually ceases a short way within the organ, and at least it seems clear that no portion of the secreting membrane itself is ever invested by it.

e. Of the distribution of the striped and unstriped fibres in the animal kingdom.—The striped fibres have been found in all vertebrated animals, and in Insects, Crustacea, Cirropods, and Arachnida. Future researches will probably discover them even more extensively diffused. But in the lower animals, especially when they are of small size, we find, as formerly mentioned, that the distinctive characters of the two varieties begin to merge into one another and be lost. The transverse stripes grow irregular, not parallel, interrupted; a fibre at one part will possess them, at another part will be without them; and even the peculiarities of the unstriped fibres are sometimes no longer to be met with in parts which are undoubtedly muscular, as the alimentary canal of small insects. It is evident that here the elementary fibres, if of their usual bulk, would be greatly disproportioned to the requirements of the case, and consequently even the minute ultimate fibre seems to be reduced within limits which remove from it those anatomical characters by which alone we can positively aver its existence. Considering, however, the circumstances which have been already adverted to in this article, as determining the size of the elementary fibre in all animals, we should not be justified in denying the same *muscular tissue* to exist here which in the higher and larger forms of life assumes the figure and bulk of the elementary fibre; and by the same mode of reasoning it may be concluded, that a tissue having the same properties as the striped fibre, and indeed essentially identical with that of which they consist, may possibly be the effective agent to which are due those wonderfully vivacious movements witnessed in the bodies of many of the minutest infusoria, where the best microscope can hardly do more than discern the organs thus put in motion. And it seems far from an unphilosophical view of the nature of ciliary motion, to refer it to the contractions of a tissue not entirely different in kind from the muscular. The elementary fibres of muscle, diminutive though they be, and hardly discernible with the eye, are yet gross organs in comparison with those which the microscope enables us to conceive capable of being formed out of them, without any necessary destruction or even injury of their contractile power.

f. Chemical constitution.—There is little to add on this subject to what will be found under the head of Fibrine. By the aid of the microscope, however, our knowledge has been rendered somewhat more precise, as to the chemical properties of the elementary structures existing in the fibres. If any substance capable of dissolving fibrine (as liq. ammoniæ) be added to the muscular fibre, this is seen to swell, to lose more or less completely its transverse and longitudinal markings, and to exhibit at once those corpuscles or cytoblasts, which before lay concealed among the sarcous elements. These corpuscles and the sarcolemma are not affected, but the sarcous elements are almost entirely taken up. But for however long a time the fibre be exposed to the alkaline menstruum, there will always remain a kind of web, of extreme tenuity and transparency, from which the sarcous elements appear to have been withdrawn. This may be seen in a transverse section of a muscle that has been thus treated, then washed and dried. I have not been able to detect in it any sort of structure.*

(W. Bowman.)

MUSCULAR MOTION.—Under this head it is intended to consider the contractility of muscle, its source, the stimuli that excite it, and the nature of the minute movements occurring during the act of contraction.

a. Of the contractility of muscle.—This subject having already been ably discussed in this work (see Contractility), I shall here confine myself to such a brief statement as may appear to be required by the advance of knowledge since the publication of the article in question.

1. *Is it a property inherent in the muscular fibre? Are we to believe in the 'vis insita' of Haller?*—The supporters of this opinion have always been exposed to the objection that in the cases of contraction adduced by them as the effect of a topical or immediate stimulus, the isolation of the muscle from all connexion with nervous fibrils has not been demonstrated. Moreover, what has generally been regarded as their strongest ground, viz. the statement that involuntary muscles are not capable of being excited to contraction by irritation of their nerves, has lately been shown by the numerous

* Dr. Williams, on Diseases of the Chest, last edition, Appendix.

[* The principal facts relating to the morbid states of Muscle will be found in the articles Heart, Morbid States of, and Hypertrophy and Atrophy. An historical sketch of the subject concludes the article Muscular Motion.—Ed.]

experiments of Müller, Valentin, and others, to be erroneous and unworthy of credit. But I have elsewhere* adduced the evidence of direct microscopical observations made on living fragments of the elementary fibre of voluntary muscle, entirely isolated from every extraneous tissue, whether nerve or vessel, to shew that this is a property inherent in this tissue, and that, whatever be its source, it is capable of being brought into action by a stimulus topically applied. Thus, when such a fragment is examined, contraction is found to occur first at its broken extremities, and if water (which has long been known to be a rapid exhauster of muscular irritability) be brought into contact with it, it is seen to absorb the fluid and to be excited to contractions, which commence at the surface. The same thing is frequently to be met with under a different form. A particle of foreign matter, as a hair or piece of dust, may be included by design or accident in the field so as to touch the side of the fibre at a single point. When this happens, the fibre will often exhibit a contraction so plain and so limited to the point touched, as to give unequivocal proof of its being the result of the irritation of pressure.

These interesting phenomena may be observed more or less satisfactorily in all animals whose fibres retain their irritability for a sufficient length of time after removal from the body, and the crab and lobster will be found the most favourably adapted for the purpose. In many reptiles and fishes, also, the steps occur slowly enough to be adequately scrutinized.

The facts in question can admit only of one explanation if it be conceded that the muscular element has been here separated from the nervous; and certainly that separation has been effected unless the nervous tubules send off from their terminal loops a set of fibrils which penetrate the sarcolemma and diffuse themselves through the contractile material within; a supposition for which there exists at present no foundation in the observations of the most diligent investigators of this subject.

They will, therefore, probably, be regarded as conclusive proof that contractility is a property inherent in the very structure of muscle, and capable of being excited to action independently of the immediate instrumentality of nerves.

The determination of this point must have a very important bearing on the question of the nature and cause of contraction, into which no small confusion has been introduced by the attempts to account for that phenomenon by various hypotheses of electrical action. That one, especially, which aims at establishing an attraction between distant points of the fibres where the nerve crosses them, (the 'zig-zag hypothesis' of Prevost and Dumas,) and which, with the wrongly interpreted facts on which it principally rests, has had an immense, though sometimes unperceived influence, ever since it was broached, on the whole question of contraction, is entirely refuted by the facts above-mentioned. There are some others, sprung out of this, which do not here require more than a passing allusion.

2. *Source of contractility: whence derived?* This important question, like the last, is debated up to the present day, but seems at length to have become disenthralled of certain loose hypotheses which have long interfered with its settlement. The discussion may be limited to such particulars as seem to be the most conclusive.

It may be observed that the contractility and development of muscle, other things being the same, are always proportionate to one another. All causes interfering with development diminish contractility. Thus muscles become atrophied and weak by disuse, by lessening their supply of blood, by cutting off their connexion with the central part of the nervous system. They are, on the contrary, augmented both in size and power by active use, during which both the vascular and nervous parts supplied to them are no doubt urged to increased activity. How is it to be decided whether these changes of contractility depend on changes of nutrition, or whether both be not a common result of changes in the amount of nervous power brought to act upon the muscles. Dr. Marshall Hall has remarked that in paralysis from disease involving the spinal cord or nerves, the wasting of the muscles is far more rapid and complete than in paralysis from affection of the brain, wherein the spinal cord and its connection with the muscles remains in a normal state; and the deduction seems at first sight plain and inevitable, that it is from the spinal cord that the contractility is derived, or at least that the integrity of the spinal system is essential to the maintenance of that property in the muscles. An ingenious experiment of Dr. John Reid's,* however, proves that this is not the case, and explains the part which the spinal system plays in respect of this property in the instances referred to. "The spinal nerves were cut across, as they lie in the lower part of the spinal canal, in four frogs, and both posterior extremities were thus insulated from their nervous connexions with the spinal cord. The muscles of one of the paralyzed limbs were daily exercised by a weak galvanic battery, while the muscles of the other limb were allowed to remain quiescent. This was continued for two months, and at the end of that time the muscles of the exercised limb retained their original size and firmness and contracted vigorously, while those of the quiescent limb had shrunk to at least one-half of their former bulk, and presented a marked contrast with those of the exercised limb. The muscles of the quiescent limb still retained their contractility, even at the end of two months; but there can be little doubt (adds Dr. Reid) that from the imperfect nutrition of the muscles and the progressing changes in their physical structure, this would in no long time have disappeared had circumstances permitted me to prolong the experiment." It is clear from this

* Phil. Trans, 1840, p. 487.

* Edinb. Monthly Journal of Medical Science, May 1841, p. 327.

description that though contractility remained, it was diminished proportionally to the wasting, in the limbs that had not been exercised.

The results of this admirably devised experiment cannot possibly be reconciled with the opinion that the spinal cord has any necessary or immediate influence in conferring contractility on muscles—that it is the source whence that property is derived. On the contrary, they show in a manner that admits of no dispute that both contractility and nutrition have been preserved together by the continued activity of the property existing in the fully developed organ at the period when the experiment was begun; and hence it is plain, and conformable to all analogy, that contractility is a property depending for its integrity on a healthy state of nutrition, which in its turn requires for its support the due exercise of the property it confers.

It might, perhaps, be argued by one disposed to uphold the electrical hypothesis of the nervous influence and muscular power, that in the foregoing experiments the galvanism supplied the place of the intercepted nervous communication, by directly furnishing the muscles with the endowment of contractility; and it is not easy to meet the objection by any decided proof to the contrary. It would be very difficult to induce oft-repeated contractions in a paraly-ed muscle by any other than electrical agency; but the refutation of this view will be found in the general arguments against the identity of the nervous influence with any form of electricity.

Viewed by the light of this and other allied experiments, the variation found in the state of nutrition of paralyzed limbs is easily accounted for. In cerebral paralysis the muscles are still subject to contraction in obedience to reflected stimuli through the spinal cord, while in the complete spinal palsy and that arising from disease of the nerves, they are never excited to action; whence their firmness in the former compared with their impoverishment in the latter case. In the paralysis of the lower limbs so graphically described by Pott, and resulting from disease propagated to the cord from the vertebræ, the early symptoms are those of irritation, and consist rather of irregular contractions, probably in part reflex, and which the patient is unable to control, than of any diminution of actual power in the limbs; and it is constantly remarked that in this stage there is no loss of size in the affected parts, but rather that in the midst of a general emaciation consequent on the patient's confinement, these limbs retain their fullness, and even appear hypertrophied. Should the malady advance to disorganization of the cord, the muscles cease to be excited. They become dead to all stimuli except such as are topically applied, and being never so stimulated, soon become flabby and wasted. Thus it would appear that the spinal cord in cerebral paralysis serves to keep up contractility in the muscles, not by supplying them with it, as from a source, but by exhausting them through the contractions it excites. It is not a charger but an exhauster through its nerves; and as exhaustion alternating with reaccumulation is necessary for healthy nutrition, and healthy nutrition induces contractility, it becomes in such cases an important though indirect agent in the maintenance of that property in the muscles. There can be little doubt that if muscles completely cut off from the nervous centres were submitted to galvanic agency at frequent intervals, they would not decrease in size, and might, if already atrophied, be even augmented in bulk and power; and perhaps some of the vaunted successes obtained by galvanism and electricity may be explained in this manner.

There appears to be no argument nor established fact on the other side which invalidates the experiment of Dr. Reid, or which does not admit of being explained on the ground which that experiment substantiates; and the whole question is still further cleared by the singular circumstance that has been often adduced, that fœtuses born without brain or cord may have their muscular system developed and active.

If, to what has now been advanced, there be added the evidence before adduced, that this is a property inherent in the very structure of muscle, and that it is capable of being exerted therein independently of all communication with other tissues, it will probably no longer remain doubtful that it is a property belonging to muscle as a tissue, and that it only requires for its perfection that nutrition should be perfect. Whatever interrupts nutrition interferes with it, and it matters little whether such interruption arise from the want of its own exercise or from deficiency of arterial supply, arising from causes either local or general. Inertness of a muscle, whether the consequence of diseased nerves or otherwise, will be attended with more or less atrophy and weakness, according to its degree, and to that alone.

For full information concerning the varieties in the intensity of this power, and in its durability in muscles after systemic death or after their removal from connexion with the nervous and vascular systems, the reader is referred to the article Irritability.

I would merely remark in corroboration of the views there maintained, that in the animal series the size of the elementary fibres and the consequent amount of their vascular supply, independently of the more or less arterial quality of the blood, is accurately proportioned to their irritability. Thus Birds, whose irritability is most exalted and most evanescent, have the smallest fibres and the most richly supplied with blood, while Reptiles, Fish, and Crustacea, in which the irritability is most enduring, have fibres of large dimensions and provided with a vascular web of small comparative size (*fig.* 286, art. Muscle). The same is true as regards the heart compared with the voluntary muscles.

b. Of the stimuli of muscle.—The stimuli which induce contraction have been classed into remote and immediate. Properly speaking, the remote stimuli are stimuli to the nerves and not to the muscles: they cause a change in the motor nerves, which are thus made to excite contraction by their immediate and topical action on the muscles. Of these the chief are volition, emotion, and impressions carried by the afferent nerves to the nervous centres and involuntarily reflected thence; but various diseases and injuries of the motor nerves, either at their origin or in their course, and pressure, heat, chemical substances, electricity, galvanism, &c. applied to their texture, are to be ranged under the same head.

The nature of the change thus induced in the motor nerves is entirely unknown. There seems, however, no ground for believing that it differs with the particular stimulus which induces it, and certainly a clear distinction ought ever to be drawn between it and its exciting cause. The nerves, when this change is induced in them, occasion the muscles to which they are distributed to contract. The stimulus they give is an immediate one, and is termed the *vis nervosa* or the nervous stimulus of muscle. It acts topically on the muscular fibre. The other immediate stimuli are physical and chemical; they are rarely exerted in the living body, except in the case of the hollow muscles. It has already been stated that trustworthy experiments have lately shown these to be under the influence of motor nerves derived from the spinal marrow, but it seems probable that some at least are normally excited to contract by direct stimulation, to one form of which, that of stretching or distension, they are peculiarly liable from their arrangement as investments to cavities. All muscles, however, may be made to contract by physical and chemical stimuli applied to their fibres.

The effects of water and mechanical pressure as immediate stimuli have been already alluded to. Chemical substances may be seen to act similarly, if they be not so powerful as to destroy the texture of the part; and it is probable that electrical forces have a like agency. An interesting phenomenon has been pointed out by Dr. Stokes,* which seems to show very clearly that contractions of voluntary muscles may be excited by an immediate stimulus in the living body. In various cases of phthisis, and in others, particularly those attended with emaciation, a sharp tap with the fingers on any muscular part is instantly followed by a contraction, evidenced by the rise of a defined firm swelling at the point struck, enduring several seconds before it gradually subsides. This is often so prominent as to throw a shadow along the skin, and for the moment it might almost be mistaken for a solid tumour. That it is limited to the point struck is full proof of its being a direct effect of the irritation, and not produced through the intervention of nerves; for a contraction excited in the latter mode would be diffused over the part to which the nervous twigs irritated were supplied, and would therefore frequently extend to some distance.

c. On the visible changes occurring in muscle during contraction.—1. *Of the changes essential to the act.*—A muscle in action becomes shorter and thicker, and it is well ascertained by experiments often repeated that these changes in its relative dimensions are accurately proportioned to one another. The whole organ neither gains nor loses in bulk.

What is true of the organ is true of the tissue—in contraction it increases in diameter and shortens in a corresponding degree. This is all that can be said in general respecting the visible features of this remarkable phenomenon. Late investigations, instead of explaining the manner in which contraction is effected, by shewing its dependence on forces previously understood, have only served to point out the inadequacy of the coarse and mechanical hypotheses which physiologists have been so prone to confide in, and to make it more than probable that they must ever be content to repose upon the fact above stated as the simplest which the most refined microscopical analysis can ever disclose.

The intimate connexion between the nerves and muscles, both in rest and action, and the exquisite organization displayed in the structure of those muscles which are most quick and energetic in their movements, have powerfully contributed to excite the hope that a clue to the discovery of the physical mechanism of contraction would one day be found. It may be thought, therefore, a subject of disappointment that when at length a close insight into its visible characters has been obtained, and the minutest particles which the best instruments can discern have been brought under observation during their state of activity, the only change that can be appreciated in them is that which was long ago known by accurate experiment to occur in the aggregate mass, viz. that they become shorter and thicker.

All muscle, after systemic death or after removal from the body, undergoes a contraction, termed the *rigor mortis*, which has received much attention in all that relates to the mode of its approach, its course and duration, and the practical bearings it presents. (See DEATH.) This phenomenon may be varied by the application of stimuli, and is eminently suited for the display of the minute changes occurring in muscle during its active state.

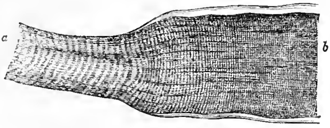
The muscle with striped fibres is peculiarly adapted for the display of these changes; for its texture not being homogeneous, but marked throughout with perfect regularity into spaces or particles so minute as to require to be very highly magnified before they can be even seen at all, the anatomist is provided with the means of detecting movements, which, without this circumstance, must have remained concealed. It is accordingly by the study of this variety of the tissue that the results just alluded to have been obtained.

When a fragment retaining its contractility is torn up into its elementary fibres, these are seen to undergo a slow movement at certain points, especially where they have suffered violence, as at their broken extremities. This movement consists of a shortening and thicken-

* On Diseases of the Chest, p. 397. See also Dr. Guy, in the new edition of Hooper's Physician's Vade Mecum, p. 92.

ing of the material composing the fibre, as is shown by the general outline of the part, but especially by the appearances visible in its interior. The transverse stripes, both light and dark, become longer and thinner; in other words, the discs expand in circumference, flatten and approximate to one another; or to use another form of expression, the fibrillæ become shorter and thicker, both in the particles composing them and the material connecting those particles (*fig.* 301).

Fig. 301.



Fragment of an elementary fibre (from the eel) partially contracted in water. Magnified 300 *diam.*

a, uncontracted part.

b, contracted part, along the border of which, at *c*, *c*, the sarcolemma is raised from the surface by the water that has been absorbed, that has thereby caused the contraction, and by it has been expelled from the contractile mass.

These changes are always local, or partial, and it is most evident from the characters they constantly present, that they are not limited to any determinate regions, points, or segments, but occur indifferently wherever the exciting cause may chance to be exerted. Neither discs nor fibrillæ appear to have the smallest share, as aggregations of particles bearing those particular forms, in producing the phenomena of contraction. A contraction is never bounded to a particular number of discs or fibrillæ, and is never accurately limited by the interval between two discs. It constantly happens that at the edge of the contracted part several discs are only partially engaged in it. A contraction generally, when commencing at the broken end of a fibre, occupies its whole width there; but when it commences at the border of the fibre it may be confined to a portion of many discs. And, further, a contraction never occupies the whole length of a fibre or fibrilla at once. A contraction excited in an elementary fibre by the contact of a hair extends into the mass equally in all directions, as we might suppose it would do, if the mass were homogeneous.

In a word, an attentive study of these interesting phenomena has convinced me that in the bare fact of contraction the *build* of the fibre is an item of no importance whatever: the exquisite symmetry displayed in the apposition of its component particles is, as it were, disregarded and overlooked, while the whole process is to be referred to the material itself, the ultimate tissue, whose property is *contractility*. This property appears to reside both in the particles and the substance connecting them.

The ultimate movements, therefore, on which contraction depends, whatever they may consist in, are molecular, and far beyond the reach of sense.

It will be perceived that this view of the subject is the only one which can harmonize the fact of contraction in voluntary muscle with the same phenomenon in structures which have no complicated internal arrangement of particles. In regarding contractility, therefore, as a property of the living muscular fibre *in general*, it is meant that it resides in it as a property without which it would not be muscle, and in such a manner that no particle, however microscopic, can be detached from muscle which does not of itself, and independently of the rest, possess this property, as long as it possesses vitality.

It follows from what has been advanced that those hypotheses which refer contraction to a force exerted between determinate but distant points of the fibre, as where the nervous fibrillæ cross it, or at intervals such as Müller* has sometimes seen in insects, must fall to the ground. They are so entirely incompatible with the facts above stated that it can scarcely be necessary to dwell at length on the other reasons for rejecting them, or on the explanation of the phenomena adduced in their support. The main fact on which they have been built is that long ago mentioned by Hales, and more recently studied with minute care by Prevost and Dumas, viz. that in the abdominal muscles of the frog detached and excited by galvanism, the elementary fibres are seen to be thrown more or less into a zig-zag form. It is evident that in interpreting what they saw these eminent physiologists mistook the relaxed fibres for contracted ones. In conducting such experiments many precautions are required, and at the best, nothing of the real process of contraction can be witnessed. As Müller correctly remarks, the muscle is too thick to be seen under a high power. Besides, the shock of galvanism causes only an instantaneous contraction, during which the muscle is so agitated that it is in vain to attempt to examine its condition. It gets out of the focus of the instrument. What is seen afterwards is not the contraction but its result, viz. an approximation of the extremities of the fibres. If the galvanic shock has acted uniformly on all the fibres (which is rare), they all remain straight; but if on a part only, those which have escaped contraction are thrown into zig-zags by having their ends brought nearer through their cellular connexion with neighbouring contracted fibres. It is most natural that the precise point of such flexures should often be determined by the passage of nerves or vessels across the fibres. This is corroborated by the circumstance that relaxed fibres fall at once into zig-zags when their ends are made to approach by mechanical means.

MM. Prevost and Dumas have themselves drawn attention to an example of shortening without zig-zags in the case of the distended abdominal muscles of the female frog before spawning. They found that the fibres of those muscles when cut across remained straight, after shortening from 145 to 107 millimetres.

* Physiology by Baly, p. 889.

Independently of the immense disadvantage at which the hypothesis in question supposes the force to act, (viz. either between the particles at the retiring angles only of the zig-zags, or between the distant angles themselves,) it seems quite inconsistent with the able experiments of Schwann, which show that the power of a muscle diminishes in a direct ratio with the degree of its contraction. With these experiments, indeed, any hypothesis is at variance which is based on the idea of an attraction between isolated and separate points or particles, as, for example, the sarcous elements, for it cannot be conceived but that such an attractive force would augment in a multiplying ratio with the proximity of the points attracted.

2. *On passive and active contraction. Passive contraction.*—Passive contraction is that which every muscle is continually prone to undergo, independently of stimuli, and by the mere quality of its tissue. The muscles are ever kept on the stretch by the nature of their position and attachments, and cannot have their ends so approximated by attitude or otherwise, as that their tendency to shorten themselves shall cease. If, for example, the rectus muscle of the thigh have its extremities brought as near together as can be effected artificially by posture, they would yet be found to approach still nearer on being freed from their attachment to the bones. This tendency to contract has been distinguished by the term *retractility*, from its being manifested by the retraction that occurs when the belly of a muscle is cut across. But, in this instance, the retraction would appear to be in part caused by an active contraction excited by the stimulus of the injury. It has also been styled *tonicity*. The passive contraction of muscles continually opposes their elongation by the action of antagonists, and restores them when that action ceases. It is that which accommodates them to an attitude artificially given, when no muscular effort is required to maintain it. When no active contraction is present in a limb, the passive contraction remains, and being brought to a state of equilibrium in all the muscles by their mutual antagonism, the limb is said to be at rest. This is the general condition during sleep. The passive contractility of muscles, therefore, is being ever exerted, without being attended by fatigue; there seems no good reason for supposing it to be a property different from active contractility; it is rather the necessary condition of that property, in its passive or unstimulated state. Passive contraction is a vital act, for it ceases with the *rigor mortis*.

Active contraction.—This is the form of contraction which is attended with those manifestations of power or force that specially characterize muscle. It is always excited by a stimulus, and is always exerted in opposition to another force within the body, which it is able more or less completely to master. The opposing force is generally the passive contractility of antagonist muscles, but it may be the elasticity of parts, or, in the case of hollow muscles, the resistance of their own contents. Active contraction is partial in extent and duration. It requires intervals of rest, being attended with exhaustion of the power which produces it, which exhaustion in the voluntary muscles is attended with the sensation termed *muscular fatigue*.

3. *Of the differences between the minute movements of muscle in passive and active contraction. In passive contraction.*—It is, perhaps, impossible in the higher animals to observe the nature of the microscopic movements occurring during the passive shortening of a muscle; but in the lower and smaller forms of life this may sometimes be accomplished. It may always appear doubtful, however, whether any contraction that may be here witnessed be entirely of the passive kind, and consequently the movements here noticed are not worthy of implicit reliance. But it is more easy and quite as satisfactory to bring a muscle under inspection, which is still in situ and in equilibrium with its antagonists; in such, contractile force is still present, though its effects are neutralized. This may be done in various small animals; perhaps the tail of small fish or of the tadpole of the common frog is the best adapted for the purpose. In the latter, when deprived of its thick tegument, I have succeeded in gaining such a view, and have found the contraction to be quite uniform throughout, the transverse stripes being stationary and equidistant. This is nothing more than might have been expected on *à priori* grounds. The contraction being the effect of the passive exercise of the property shared equally by all parts of the tissue, would be equal in equal masses, and as the elementary fibres are of precisely equal width and substance from end to end, no part of them could predominate in action, as long as no special stimulus was applied. It may be concluded, therefore, that passive contraction is attended by a movement absolutely uniform throughout the whole mass of an elementary fibre or of a muscle.

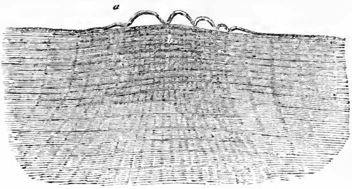
In active contraction.—The case is far otherwise in active contraction, as may now be considered proved by a considerable body of evidence.

It might be argued, prior to direct proof, that active contraction, being the answer to a stimulus, must be partial, at least at its commencement, since no stimulus can be applied at the same instant to every particle of a muscle.

Certain features of the contractions witnessed in fragments removed from the body, and examined in water under the microscope, have a close bearing on the present question. It has been already said that such contractions are uniformly partial; but they present two further varieties, either remaining in the part where they first occur, or leaving it as they engage others in the neighbourhood. The accidental circumstances under which the fragments are placed explain these varieties. In the former case the fragments are free to move; their ends approach in proportion to the amount of contraction, and as there is no force to extend them again when the contractile force ceases to be manifested in them, and advances to fresh parts, the contraction has the appearance of being permanent. In the latter case, certain parts of the fibre (as its broken extremities) are fixed more or less firmly, so as to offer a resistance to the contraction that takes place, this resistance enabling the contractile force advancing to new parts to obliterate the traces of contraction in the parts in which it is subsiding, by stretching them. The ends usually become fixed in consequence of their being the first to thicken from contraction and from their thus receiving the pressure of the lamina of mica or glass with which it is requisite to cover the object, and they are the first to contract, because irritated both by being broken and also by the water, which is absorbed soonest where the sheath is deficient. This fixing of the ends brings the fibres in question nearly into the condition under which they exist in the living body, where it has already been explained that there is always a resistance to be overcome in active contraction. This particular variety of the phenomenon, therefore, deserves special study. Those animals whose muscles are most tenacious of their contractility are the best suited for examination, and among these the young crab or lobster may be most easily obtained. In an elementary fibre from the claw, laid out on glass, and then covered with a wet lamina of mica, the following phenomena are always to be observed. The ends become first contracted and fixed. Then contractions commence at isolated spots along the margin of the fibre, which they cause to bulge. At first they only engage a very limited amount of the mass, spreading into its interior equally in all directions, and being marked by a close approximation of the transverse stripes. These contractions pull upon the remainder of the fibre only in the direction of its length, so that along its edge the transverse stripes in the intervals are very much widened and distorted. These contractions are never stationary, but oscillate from end to end, relinquishing on the one hand what they gain on the other. When they are numerous along the same margin they interfere most irregularly with one another, dragging one another as though striving for the mastery, the larger ones continually overcoming the smaller, then subsiding as though spent, stretched again by new spots of contraction, and again, after a short period of repose, engaged in their turn by some advancing wave: this is the first stage of the phenomenon. (*Fig.* 302.) The contractions increase in number and extent, and gradually engage the whole substance of the fibre. There is still the same struggle, the same alternate action and repose in individual parts, but as the contractions by degrees predominate, the ends of the fibre are drawn more and more near, (intermediate portions by their contraction receiving some of the pressure,) until at last the whole fragment is reduced to a third of its original length, and stiffened with the *rigor mortis*.

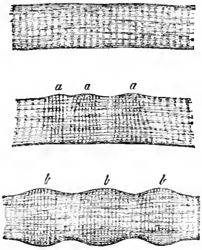
The muscular tissue in these animals is very tough, but where it is more fragile, as in the Frog, it may give way in the intervals between spots of contraction, and become ruptured and disorganized in various degrees.* In fishes I have seen a succession of phenomena similar to what has been described in the Crab; waves of contraction advancing and receding, but gradually augmenting in bulk, till the whole fibre was finally contracted. (*Fig.* 303.)

Fig. 302.



Border of an elementary fibre of a young Crab, shewing a spot of contraction (b) and the sarcolemma elevated in the form of bullæ by the expressed water (a). Magnified 300 diam.

Fig. 303.



Stages of contraction seen on one occasion in an elementary fibre of the Skate. The uppermost state is that previous to the commencement of contraction.

a, a, a, successive 'waves' of contraction seen moving along one margin of the fibre, marked by a bulging of the margin, by an approximation of the tranverse stripes, and by a consequent darkening of the spots.

b, b, b, similar 'waves' still moving along the fibre, but engaging its whole thickness.

In all these examples, as long as the ends of the fragment are fixed, and will not yield to the convellent force, that force is seen to be exerted in a momentary manner in successive portions of the mass. In proportion as they yield to it, the resistance which enabled the contraction of new parts to stretch those from which it was receding is removed, and the appearances of contraction remain. A distinction is required between the contractile force and the contraction resulting from its exercise. The latter will be permanent, if no force from without be exerted to obliterate it by stretching, for a contracted muscle has no power of extending itself; there is no repellent force between its molecules. From these phenomena, therefore, it is possible to eliminate the appearances resulting from a subsided force, and to judge of

* Phil. Trans. 1840, p. 490, pl. xix. fig. 75.

the mode and duration of action of the force itself. Thus sifted, they prove that, even when directly stimulated by water after removal from the body, a muscle contracts in successive portions, never in its totality at once, and that no particle of it is capable of exhibiting an active contraction for more than an instant of time.

The appearances presented by muscle that has been ruptured by its own inordinate contraction in fatal tetanus in the human subject will supply the link wanting to connect the foregoing phenomena with those occurring in healthy contraction during life: for tetanic spasm differs from sustained voluntary contraction only in its amount and protracted duration, and in its being independent of the will; none of which circumstances are of essential importance in regard to the nature of the act of contraction itself.

The muscles are so arranged in the body that no amount of contraction which the mechanism of the bony and ligamentous framework will permit one of them to undergo, can by possibility occasion the rupture of a relaxed antagonist: to be ruptured the antagonist must be itself contracted. But a muscle, if contracting beyond its natural amount, may be so resisted by mechanical powers, in or out of the body, as to rupture itself. Hence, the contraction of a muscle is a necessary condition, and generally the essential cause of its own rupture: the other condition being a force greater than the tenacity of the ruptured part, holding its ends asunder; this latter may be either the active or passive contraction of antagonists, or mere mechanical resistance. But it is evident that for a muscle to be ruptured by its own contraction, that contraction must be partial, as is shewn in the case of the Frog's muscle already mentioned. An examination of muscle ruptured in tetanus is found to bear out these observations in the fullest manner.* The elementary fibres present numerous bulges of a fusiform shape, in which the transverse stripes are very close. These swellings or contracted parts are separated from one another by intervals of various lengths, in which the fibre has either entirely given way or is more or less stretched and disorganized. These appearances are met with after all contractility has departed; they are the vestiges of the spasm during life. Yet in other muscles, which have been likewise convulsed, but not ruptured, they are not found. Their presence is, therefore, the result of the rupture. They admit only of the following explanation: the contractile force has operated at the points contracted, and by its excess the intermediate portions have been stretched to laceration. Having once given way, the contracted parts have become isolated, and can no longer have been extended after the subsidence of their contractile force; they consequently retain the form and appearances they possessed, when surprised, as it were, by the rupture they have themselves produced of the intervening parts.

Supposing, for a moment, that active contraction were a universal and equable act, and that by the superior power of an antagonist a weak muscle had been ruptured, the appearances resulting would manifestly be entirely different from those now detailed. The fibres beyond their ruptured point would have their transverse stripes uniformly approximated.

From the preceding facts I conclude, 1st, that active contraction never occurs in the whole mass of a muscle at once, nor in the whole of any one elementary fibre, but is always partial at any one instant of time; 2dly, that no active contraction of a muscle, however apparently prolonged, is more than instantaneous in any one of its parts or particles; and therefore, 3dly, that the sustained active contraction of a muscle is an act compounded of an infinite number of partial and momentary contractions, incessantly changing their place, and engaging new parts in succession; for every portion of the tissue must take its due share in the act.

Two phenomena yet remain to be mentioned, which, by admitting of a satisfactory explanation on this view of the subject, give strong testimony to its correctness. The first is the muscular sound heard on applying the ear to a muscle in action. It resembles, according to Dr. Wollaston's apt simile,* the distant rumbling of carriage wheels, or an exceedingly rapid and faint tremulous vibration, which, when well marked, has a metallic tone. It is the sound of friction, and appears to be occasioned by those movements of the neighbouring fibres upon one another, with which the partial contractions must be attended in their incessant oscillations. The other phenomenon is one, the existence of which has been recently ascertained by MM. Becquerel and Breschet,† viz. that a muscle during contraction augments in temperature. They have found this increase to be usually more than 1° Fahr., but sometimes, when the exertion has been continued for five minutes, as in sawing a piece of wood, it has been double that amount. This development of heat seems to be in a great measure attributable to, and even a necessary consequence of, the friction just alluded to.

Thus it would appear that active contraction consists in a disturbance of that state of equilibrium ordinarily existing in muscles when at rest; that their different portions successively undergo momentary contractions, and that there is always a considerable part of each fibre uncontracted. This will account for the remarkable fact that detached fragments of the voluntary fibre will contract by two-thirds of their length, though an entire muscle, in its natural situation, cannot shorten by more than one-third. This great capacity of contraction in the *tissue* would be without a purpose, if it were not that it only admits of momentary exertion, and therefore requires that in the *organ* successive parts should take up the act, and by so doing, render it, as a whole, continuous. In an active fibre the contracting parts are continually

* Phil. Trans. 1841, p. 69.

* Phil. Trans. 1811.

† Recherches sur la chaleur animale, au moyen des appareils thermo-electriques; par MM. Becquerel et Breschet, Membres de l'Institut. Archives du Museum, tom. i. p. 402.

dragging on those in which the contractile force has just subsided, and which intervene between them and the extremities of the fibre. These are thereby instantly stretched, and come to serve the temporary purpose of a tendon; but one which resists extension more by its passive contractility than by its mere tenacity. It is these parts which in tetanic spasm suffer laceration; which happens in consequence of the contraction excited by the vis nervosa, being then too powerful to be resisted by the passive contractility.

The preceding account of the minute changes occurring during contraction rests on data furnished by the striped form of muscular fibre; but there is nothing contained in it, which seems at variance with the little that is positively known regarding the contractions of the other form. The differences between the contractions of the two varieties are almost certainly confined to the manner of exercise, and do not extend to the essential nature of the act. Though the unstriped fibre has not been studied by the microscope during its active state, with the same success as the other, yet the similarity of the gross changes observed in it by the naked eye, to those seen in voluntary muscle, forbid us to doubt the identity of the phenomenon, in all that essentially constitutes it an act of contraction.

From the knowledge we possess, we are perhaps entitled to hazard some further conjectures respecting the differences in the mode of exercise of the contractile power in different cases. In whatever that mysterious power may consist, it would appear that the structural modifications of the two kinds of fibres are intimately connected with the manner in which it is capable of being exerted. Wherever the striped structure occurs, we witness an aptitude for quick, energetic, and rapidly repeated movements, while, where it is deficient, they are sluggish, progressive, and more sustained. The varieties in the character of contractions performed by striped muscles are very striking, especially that of the heart, as compared with the prolonged action of the voluntary muscles. In both there is an alternate momentary action and repose of every contractile particle, but in the heart the contraction is universal at one instant, and the repose equally universal at the next, while, in the prolonged action of the voluntary muscles, contractions of certain parts of each fibre always co-exist with repose of other parts.*

The contractions of voluntary muscles differ greatly from one another in duration, energy, and extent. Nothing is more wonderful, if it be well considered, than the power the will possesses of regulating the amount of stimulus which it is able to give to the muscles, and that of transmitting it with uniformity during a given period. Dr. Wollaston† was of opinion, that the phenomenon of the muscular sound affords a proof that the *duration* of a muscle's contraction depends on the application to it of a succession of distinct impulses; and this idea, according very nearly, as it does, with the later evidence of observation, appears, on the whole, the most satisfactory that has been advanced on this abstruse subject. He also thought that the intensity of a contraction corresponds with the rapidity with which these impulses are transmitted to it, and this likewise may be, in part, true. But there is, in addition to this, in all probability, a difference in the intensity of the stimulus itself in different cases, producing a difference in the size of each wave, a difference in the amount of contractile energy exerted in each, and a difference in the rapidity with which the waves oscillate along the fibre. The *extent* of the contraction (the duration and intensity being the same) will manifestly depend on the amount of the length of the fibre which is contracted at once. But we are ignorant whether this variation in amount is effected by a variety in the number of waves, or in the extent of the fibre engaged by each of them.

* By the expression 'universal at one instant,' I do not mean *absolutely* so, for observation and the presence of the muscular sound both declare that the contraction, even of the heart, though so apparently momentary, is progressive.

† Philos. Trans. 1811.

The ancients appear to have been quite ignorant of the nature of muscles. Plato and Aristotle attributed to them so trivial an use, as to think that, like fat, or a kind of clothing, they kept out heat in summer and cold in winter.* The nerves and tendons were confounded with the muscles, as they commonly are at this day, by the vulgar. Borelli, in his elaborate work, *De motu animalium*,† thinks it requisite (in 1734) to adduce arguments against the doctrine that muscle and flesh are different, the former composed of an aggregation of tendinous fibres, the latter a certain villous substance incrusted by the blood upon their exterior, a fact showing the extremely loose notions that prevailed on this subject even up to a comparatively recent period. The fibres so obviously composing the essential part of muscle have been the subject of the most extraordinary speculations, probably ever since it was discovered that they were endowed with contractility, the property which, on a superficial aspect, seemed the most closely associated with life. And it is by no means surprising, that when the microscope began to open a new world to view, it was applied with ardour to the investigation of this tissue. It is not easy to appreciate justly the accounts given of it by some of the earlier micrographers, in consequence of the indeterminate meaning of many of the terms they employed, and the imperfection of the means at their disposal for accurate definition and measurement of the objects they describe. Robert Hooke, however, had probably a correct general knowledge of the elementary fibres of voluntary muscle, and possibly even saw the fibrillæ into which they often split; for we find him in 1678 speaking of the "fibres which seemed like a necklace of pearl in the micro-

* Vesalius, vol. i. p. 182.

† Propos. ii.

scope."* Previous to him no author appears to have examined them. But Leeuwenhoek,† his friend and correspondent, makes continual mention of his examinations of the muscular fibre of various animals. This acute and enthusiastic observer clearly recognized the important fact, that each elementary fibre is a perfect and separate organ in itself; he was astonished to find that in all animals, the largest as well as the smallest, these fibres are excessively minute; he discovered the manner in which they are aggregated, and invested by areolar tissue; and by boiling and drying a muscle and then making tranverse sections of it, he ascertained those of voluntary muscle to be polygonal and solid. He described the cross lines, which he conceived to be on the surface only and to be the coils of a spiral thread. To this structure he attributed the active power of the fibre, comparing it to an elastic coil of wire. He further saw the longitudinal lines visible on the elementary fibre, and considered them to be an evidence of a still minuter composition by fibrillæ. All these points are well illustrated by figures, which leave no doubt of his meaning; but, as his results are scattered through a great number of letters, much of what he accomplished seems to have been overlooked by later writers. Leeuwenhoek concluded that in contraction the cross markings approximate, but I cannot discover that he speaks of having seen this. He confounded the cross markings seen on tendon with those of muscle, and fell into the prevalent error of attributing contractility to the tendons. Malpighi incidentally mentions the minute structure of muscle in only one passage of his works.‡ He appears to have seen the transverse stripes of the elementary fibre, and to have also likened them to those of tendon. Contemporary with Leeuwenhoek was de Heide,§ who, in 1698, published some observations on muscular fibre, describing and figuring the transverse markings. In 1741, Muys,|| in a voluminous work, with good plates, gave all that was previously known, and added many observations of his own. His book, however, is learned rather than profound. He separates the elementary fibres into the simple and reticulated, and seems to have considered the stripes to be the effect either of minute zigzags during contraction or of a spiral form of the fibrillæ.

Prochaska¶ next produced an excellent treatise on muscle, in which he explained, with great clearness, the figure, size, and solidity of the elementary fibre, and the appearances of the fibrillæ into which it divides. He fell into the error, however, of confounding the transverse markings in the intervals of the discs, with other creasings or flexuosities which never exist in the living body, but continually present themselves, in the dead fibre, from mechanical causes. All these he attributed to lateral pressure made on the fibre and fibrillæ by vessels, nerves, and areolar tissue, which he erroneously imagined to penetrate the interior of the fibre. Prochaska injected muscle with great success,* and found the vessels so numerous that he was induced to believe contraction to depend on distension of the vessels, throwing the fibrillæ into zigzags.

Fontana,† a few years afterwards, gave a much more accurate account of the fibre than had previously appeared, and one remarkable for its simplicity. According to him the elementary fibre consists of fibrillæ, marked at equal distances by dark lines, which by their lateral apposition occasion the appearance of cross striæ. Hence he styled the fibre a *primitive fasciculus.* By this term, which has been generally adopted, undue importance is attributed to the longitudinal cleavage, for the elementary fibre may as justly be called a *pile* as a *bundle.* It is not, however, in strictness, either one or the other.

In the period that has elapsed since Fontana's description was published, up to the last few years, no real addition has been made to our knowledge, and so discredited or forgotten, at least in this country, were the labours of the authors already enumerated, that the anatomy of the muscular fibre was taken up as a new inquiry in 1818 by Sir Everard Home and Mr. Bauer.‡ The latter very excellent observer must have been deceived by the imperfection of his glasses, which do not seem to have been adapted to so minute a structure, for his results, as published by Sir E. Home, have had the effect of retarding rather than of advancing our knowledge, by raising doubts as to the credibility of any conclusions founded on microscopical research. In 1832, Dr. Hodgkin and Mr. Lister§ re-discovered the transverse markings on the elementary fibre of voluntary muscle and of the heart, and pointed out, as Muys and Fontana had done, that their presence was a character by which this could be distinguished from the fibre of the uterus, bladder, &c., which latter they consequently denied to be muscular. Since then, many inquirers, both in this country and abroad, have taken up the subject with improved instruments.

Among those who have arrived at conclusions similar to those of Fontana may be mentioned the names of Lauth, Müller, Schwann, and Henle. Others, however, have entertained very opposite and, as I believe, erroneous views of the composition of the fibre. Mandl¶ conceives the cross markings to be produced by a

spiral thread of areolar tissue investing the fibre, and Mr. Skey* describes them as an external structure, independent of the fibrillæ, which he believes to be arranged in band-like sets around a glutinous substance in the axis of the fibre. Ficinus† falls into the old error of Prochaska, of imagining the striæ to be the result of minute flexures of the fibrillæ, and, like him, he confounds with them the secondary flexures of the whole fibre. Hence, says he, the appearance of globules or particles is false, and only exists during contraction. Other opinions still I have had occasion to allude to in the course of the article Muscle, which, as before remarked, is founded on observations which have been now two years before the public.‡

All the best observers are agreed as to the existence of certain appearances, and the discrepancies we encounter in the interpretation of them ought not to bring discredit on all researches of this sort. They place, indeed, in a strong light the difficulty of the inquiry, and the necessity for repeated, varied, and unbiassed observation, with the best instruments we can command. But we are too familiar with conflicting and even opposite statements concerning visible facts, occurring daily under the eyes of every one, to suppose it possible that any kind of investigation will ever be free from those causes of error, which lie in man's nature, in his own *microcosm*, and the effects of which can only be neutralized by the common consent of numerous independent observers. As for those difficulties, whatever they may be, which are inherent in the nature of the subject, we cannot doubt that they will be, in due time, appreciated and overcome.

Some of the opinions concerning the nature of contraction, entertained by the earlier observers, have been already mentioned; another, which seems to have been grafted on the doctrine of the vital spirits, was, that these spirits were directed into the fibres and distended them, thus causing them to tumify and shorten. Accordingly, some (as Robert Hooke and Cowper) considered each fibre or fibrilla to be hollow; which need not excite surprise, when we find the great Mascagni § believing each to be a lymphatic vessel. The first hint of another very noted hypothesis is to be found in the Memoirs of the French Academy, 1724:—L'Abbé de Molières there says,|| "Les fibres charnues qui s'étendent selon la longueur du muscle, et dont le raccourcissement fait son action, se divisent en un grand nombre de petites fibres de même nature longitudinales aussi, et qui sont liées les unes aux autres par des filets nerveux transversaux disposés le long des fibres de distance en distance. De plus, les petites fibres charnues ne sont pas droites, mais pliées en zigszags, dont les angles se trouvent aux endroits, où sont les filets transversaux." Hales* examined the abdominal muscles of small living frogs, and saw them thrown into zigzags during contraction, as he imagined; but he mistook the uncontracted for contracted fibres, as I have explained.† Prevost and Dumas, at a later period,‡ described the same zigzag flexure of the fibres during contraction, and further imagined it to be an electrical effect produced by the passage of the nerves across them at their angles of flexure. This doctrine was too captivating not to obtain very general credence, especially as it seemed to fall in with a notion, at that time very current among speculative physiologists, that the nervous influence is a form of electricity. But its validity has of late begun to be questioned; Professor Owen,§ in small filariæ and in a species of vesicularia, observed a fact opposed to it, viz. the bulging of the (unstriped) fibres near their centre, without their falling out of the straight line, in contraction. A similar fact was observed in the case of the (unstriped) muscles of the Polypifera, by Dr. A. Farre;|| and Dr. Allen Thomson,¶ on repeating the experiment of Hales and Prevost on the Frog, "observed single fibres continuing in contraction, and being simply shortened, and not falling into zigzag plicæ; and he was led to suspect, from this and other circumstances, that the zigzag arrangement was not produced until after the act of contraction had ceased." M. Lauth, after a careful investigation, concludes** that a fibre may shorten with or without zigzag inflection. Such, I believe, was the state of this question in 1840, when I published the observations,†† on part of which the account of the nature of contraction, given in the present article, is principally based. In the following year I added‡‡ a note, on the appearances met with in human muscle ruptured by tetanic spasm, and which seemed to me to prove that the conclusions I had previously drawn from the phenomena of the *rigor mortis* were true as regards the act of contraction, as it occurs in the *living body*.

MUSCULAR SYSTEM, (Comparative Anatomy of).—The muscular system of animals, as the term is generally understood, is composed of masses or fasciculi of highly irritable filaments, by the contractions of which the movements of the body, whether voluntary or involuntary, are effected, and the arrangement of these moving powers, their size and strength, forms and general disposition, must of course vary *ad infinitum* in the different classes of animals, in conformity with the varieties of their external form, or the innumerable kinds of apparatus conferred, for special purposes, upon particular tribes or even species of living beings. Of these detailed accounts are elsewhere given in those articles which treat of the structure and anatomy of each class entering into the composition of the animal kingdom. Nevertheless, it has been deemed advisable, upon the present occasion, to collect together in one view the principal facts connected with general myology, and to state, as briefly and concisely as the nature of the subject will allow, those grand physiological points which an extended review of the comparative organization and development of the muscular system reveals to the anatomical observer, in order to concatenate the leading facts recorded in other pages of this work.

It may be laid down as an axiom universal in its application, that *the condition of the muscular system in any race of animals must be dependent upon, or at least in strict conformity with, the development of the nervous apparatus, by the influence of which muscular movements are excited, controlled, directed, and associated.*

Thus, as we advance from lower to more elevated forms of living creatures, it is easy to perceive that in exact proportion as the nervous system makes its appearance, and becomes progressively more elaborately organized, the muscles themselves become developed and assume a perfection of structure and precision of movement adapted to the increasing exigencies of the animal economy; nay, it has now been satisfactorily established that even among the highest races of the animal creation, during the progress of embryo development, the most intimate relation is observable between the state of the nervous centres and the condition of the nascent muscles as they become gradually formed and perfected. In the lowest Zoophytes where nervous fibres of any kind are not perceptible, even under the most rigid microscopical examination, the contractile tissue of the body is equally diffused and devoid of aggregation into filaments or fasciculi of muscular fibre, and precisely under the same conditions the first rudiment of the vertebrate embryo, being as yet entirely devoid of nerves, is also destitute of distinct muscles, the movements of which could only be associated and rendered efficacious by means of nervous intercommunication; and this complete want of aggregation of the elements of muscular tissue is as remarkable throughout all the *Acrite* division of the animal world as it is in the nervous matter entering into the composition of their bodies, which, although its presence is not to be detected by our senses, is reasonably supposed to exist in a diffused state even in the lowest tribes of animated beings. As soon as nervous threads become apparent, and long before ganglionic masses of neurine are developed to such an extent as to entitle them to be regarded as centres of innervation, the muscular tissue, in like manner, assumes a different and far more perfect character; the elementary molecules composing muscular fibre are then distinctly visible, and assuming a definite arrangement become grouped in longitudinal series, exhibiting contractile bands and fascicles placed in precise directions, and capable of effecting movements of a more decided character than could possibly be exercised in creatures deprived of nervous cords, whereby the contractions of numerous muscular fasciculi might be associated and made to cooperate for the accomplishment of a given purpose.

Moreover, it must be obvious that, in that great division of the animal creation which is characterized by the existence of nervous filaments, the ganglionic centres being as yet imperceptible, or at least where any have been detected, in a very rudimentary state of development (the Nematoneura of Professor Owen); such a condition of the nervous apparatus involves, as a necessary consequence, important circumstances connected with the general economy of the beings so organized as regards their means of relation with the external world. Having as yet no ganglia developed sufficiently important, from their size or situation, to merit the title of brains, or fit to be regarded as constituting a common sensorium, whereunto information derived from remote parts of the body may be conveyed, localized instruments of sensation would be as yet superfluous, and consequently, with the exception of the generally diffused sense of touch which, from its extreme delicacy, seems in these lowest forms of existence to supply to a certain extent the deficiency of other means of perception, instruments of sensation are not as yet conferred. The presence of a localized organ of sense, analogous to an eye or an ear, must obviously be useless to a creature possessed of no sensorial centre, to which information, derived through the medium of that sense, may be transmitted, and organs of the higher senses are, therefore, as yet entirely wanting throughout the NEMATONEUROSE division of the animal kingdom,* as, *à fortiori*, they are necessarily deficient throughout the ACRITE classes. In like manner the existence of external locomotive members, moved by any powerful or elaborately constructed muscular apparatus, is not to be expected in animals that possess not ganglia capable of presiding over voluntary muscular motion. Limbs, therefore, properly so called, are not as yet developed; and, if in some of the most perfect Epizoa, the rudiments of such structures become apparent, it is only because the animals possessing them are so nearly allied to the Articulata, in their general structure, that the nervous ganglia in them are beginning to be developed, and thus they can only be looked upon as the transition steps leading by an almost imperceptible gradation from one great type of animal organism to another of a more elevated character.

In the ARTICULATA (HOMOGANGLIATA, Owen), brains, or ruling ganglionic centres, for the first time make their appearance in a sufficient state of development to correspond with organs of sense of a localized character, or to animate systems of muscles adapted to wield locomotive limbs, and combine complex actions now essentially connected with the more perfect attributes bestowed on forms of life capable of more extensive relations with surrounding objects. Still, however, an exact correspondence exists between the progressive expansion of the nervous centres and the gradual appearance of limbs moved by a distinct muscular apparatus, which become progressively superadded to the annulose body or trunk of the articulated animal, and in precisely the same manner does the advancement of the nervous system from a less perfect to a more concentrated condition evidently precede the appearance of external appendages, subservient to the exercise of more exalted powers of sensation, or increased capabilities of locomotion. The humblest annulose forms, as for example the *Leech* and the *Earthworm*, possessing, as they do, a nervous system consisting of an extended series of numerous pairs of feeble ganglia, none of which are as yet sufficiently potent to control any complex muscular apparatus, or to appreciate impressions derived from without with much nicety or precision, are necessarily deprived of outward limbs, or complicated instruments of sense; their soft and flexible integument is unequal to sustain any jointed members whatever, and the first rude vestiges of simple eyes, *ocelli*, are all that can be allowed for the purposes of vision. By degrees the nervous ganglia becoming fewer in number as they coalesce into larger and proportionately more energetic masses, the moving organs of the body become perfected in the same ratio; limbs, almost impotent as yet, but still sketching out the articulated legs hereafter to be perfected, make their appearance, and the apodous Annelidan, the humble inhabitant of the water, is promoted to a terrestrial existence; jointed feet at length become appended to the segments of the still worm-like body, small and feeble at first, as in the *Iulus terrestris* and the other vegetable-eating MYRIAPODS, but speedily, in proportion as the individual segments of the body become enlarged and strengthened, and the motor ganglia acquire increased energy, assuming larger dimensions and greater perfection of structure, until the annulose animal attains the strength and activity of the carnivorous *Scolopendra*, and becomes fitted for a life of rapine and destruction.

Advancing from the *Scolopendra*, which as yet is only able to creep upon the surface of the ground, we are at length conducted to the far more active and highly gifted races of INSECTS, properly so called, in which the development and perfection of the muscular system is advanced to a condition adapting these wonderful little beings to an aerial existence, and in making the transition from Myriapod to the Insect the carrying out of the same great law is most obviously and conspicuously illustrated. The nervous ganglia, still numerous and proportionately feeble even in the *Scolopendra*, become in the aerial insect reduced in number until they are collected into a few large and potent masses; senses of a wonderfully exalted description, correspondent with the increased size of the encephalic ganglia, replace the simpler organs of the less exalted Articulata; those segments of the body whereunto locomotive members are appended coalesce and become fused together into a dense and strong thoracic armour able to sustain the violent efforts of the powerful muscles now re-

* In laying this down as an important physiological axiom, a few words of explanation will be required by those, who, adopting Ehrenberg's views, regard the red spots observable upon numerous Animalcules and Zoophytes as being the eyes of those creatures. That many species of such animals possess *red spots* occupying definite positions upon different parts of their bodies, no one will be disposed to deny who has paid the slightest attention to their economy and organization; but that these red spots are *eyes*, we think, for the reasons above stated, may reasonably be doubted, more especially as it has not even been proved by observation or experiment that they possess either the structure, or the functions of any visual apparatus, with which we are acquainted.

quired for flight; the corresponding ganglia contained within the thorax exhibit a size and development proportioned to that of the muscles they are destined to animate; and the winged Insect becomes thus competent to the exhibition of feats of strength and activity not to be paralleled in any other race of living beings.

On taking a survey of the molluscous or of the vertebrate divisions of the animal creation, the same great law is every where apparent, and we are reminded, on all hands, that a strict parallelism exists between the condition of the locomotive system, whatever may be its character, and the perfection of the nervous apparatus, whereby muscular movements are controlled and directed. As a necessary consequence of the above intimate and inseparable relation, which invariably exists between the organs of motion and those of innervation; and allowing, as modern Zoologists all admit, that the nervous system, whatever may be its condition, is to be regarded as the ruling primary portion of the animal economy, we are naturally led, therefore, in reviewing the muscular system generally, to take this great physiological axiom as our guide, and beginning with the simplest forms of life to trace the first appearances and successive complication of the motor organs as we advance through the different classes of animated beings.

In the Cuvierian classification of the Règne Animal all the lower animals, originally confounded under the general name of Zoophytes, are included in one great division, called RADIATA, from the circumstance that many forms of these animals exhibit more or less of a radiated arrangement in the general outline of their bodies. For the term RADIATA, in the article ANIMAL KINGDOM of this Cyclopædia, Dr. Grant has substituted that of "CYCLONEURA," acknowledging, at the same time, that the name selected by him was of equally partial application, and consequently unsatisfactory; inasmuch as, in the great majority of the animals ranged under it, so far from any nerves being visible, "disposed in a circular manner around the oral extremity of the body," not a trace or vestige of nervous fibre is by any means discoverable; and, moreover, many of the animals thus grouped under one denomination are so remote and dissimilar from each other in every feature of their economy, that it is impossible to regard them even as being organized according to the same type. As regards the condition of their muscular system, the most striking differences are at once perceptible; the *Sponges*, the *Polyps* properly so called,* the *Polygastrica*, and the *Acalephæ*, have the texture of their bodies so soft and gelatinous, that not a muscular fibre is by any means apparent in any of them; while, on the other hand, the *Echinoderms* have muscular systems constructed upon exceedingly elaborate and complex principles. Taking the nervous system for our guide, it is at once evident that the presence of nerves and of muscles goes hand in hand, and the RADIATA of Cuvier or the CYCLONEURA of Grant is at once separable into two great groups, one division being without either visible nerves or muscles, while the other is found to possess both. Classifying them, therefore, according to this principle, and adding to the list of radiated animals some which, in the article ANIMAL KINGDOM, have, as we think, been erroneously included in the Diploneurose (articulated) subkingdom, they readily range themselves under the following denominations:—

ACRITA.

Animals with neither nerves nor muscles.

Agastrica.
Polypiphera.
Polygastrica.
Acalephæ.
Sterelmintha.

NEMATONEURA.—Animals possessed both of nerves and muscles, either without perceptible ganglionic centres of innervation, or where these do exist, they are extremely rudimentary, and not arranged in any parallel series. This division will include

Cœlelmintha,
Bryozoa,
Rotifera,
Epizoa,
Echinodermata.

The term *Agastrica* is here proposed to include those lowest forms of animal existence which obviously form the transition from the Vegetable to the Animal Kingdom; many of them indeed seeming rather to belong to the former than to the latter division of the organized world. Such are, for example, the confervoid animalcules, which, in their structure and mode of reproduction, are evidently nearly allied to vegetables, although from the seemingly spontaneous movements of which some, the Oscillatoriæ, &c. are capable, they have been claimed by Zoologists as belonging to their department. The *Sponges (Porifera*, Grant) are equally allied to vegetables in the nature of the living parenchyma that invests and forms their porous or reticulated skeletons; and most intimately related to these, notwithstanding the different texture of their framework, are many of the lithophytous *Corallines* and *Fungiæ*, the solid portions of their skeleton being in like manner deposited in an organized soft tissue, the animal nature of which is by no means as yet clearly established. All the above plant-like forms agree, however, in one grand and striking circumstance,—they are devoid of any stomachal or digestive cavity, a feature of their economy which of itself would be sufficient to raise a doubt whether they are strictly entitled to be regarded as animals or classed with the vegetable creation.

* In the article referred to, polypiform animals, with ciliated tentacula around the mouth, are classed with the *Polypifera*. Recent observations made by Lister, Milne Edwards, Ehrenberg, and Dr. Arthur Farre, have, however, since shewn such creatures to be so far removed in their general organization from the true Polyps, that they now constitute a distinct class under the title of *Bryozoa*.

We need scarcely say that in the *Agastrica* no muscular system whatever can be detected, the living portions of their bodies being entirely made up of a soft granular parenchyma which only dubiously exhibits contractile movements under any circumstances.

In the *Polypiphera* we find a very extensive group of animals naturally allied to each other in the general details of their economy, but offering very great diversity of structure and external form. In the simplest or gelatinous *Polyps (Hydridæ)* the acrite condition of the nervous and muscular tissues is most conspicuously exemplified. Examined under the microscope, the entire substance of the minute gelatinous bag composing the body of the Hydra seems to consist of a glairy material, wherein are suspended coloured globules that constantly change their relative positions, and move about from place to place as the creature contracts, or extends different parts of its substance, but not a fibre or filament is discernible passing in any direction, nevertheless the movements of the Hydra appear to be performed with facility, and its powers of locomotion are considerable.

In the *Alcyonidæ* and other compound cortical *Polyps*, muscles of any kind are equally invisible, and the contractions observable either in the substance of the common body or in the numerous hydriform mouths that minister to the support of the general mass, seem to be entirely due to the approximation of molecules diffused through the entire substance of the animal, rather than dependent upon any thing like muscular structure; nevertheless it has been stated, though perhaps erroneously, that some families (the *Pennutulidæ*) are able to swim from place to place by consentaneous movements of the polyps and polyp-bearing arms with which many species are provided.

The tubular Polyps are equally devoid of any thing like muscular fibre, nevertheless the soft and uncalcified membrane that connects the Polyps to the cells wherein they are lodged, and the Hydriform Polyps themselves, are endowed with the capability of performing all the movements required to protrude the flower-like bodies from the cups that contain them, and to seize and swallow the materials required for their support.

But in every group of animals, as we approach the most highly organized members of that group, we find the characters of a more exalted type of organization beginning to manifest themselves, and thus in the *Actiniadæ*, which are obviously osculent between the Acrite Polyps and animals possessing a true muscular system, a fibrous arrangement of the contracting portions of the body becomes very distinctly recognisable, and a nervous filament may be displayed under favourable circumstances passing round the oral extremity of the creature, and thus closely approximating the nematoneurose type of structure. The infusorial animalcules (*Polygastrica*, Ehren.) seem, as far as relates to their muscular system at least, to be strictly acrite animals, but such is their extreme minuteness, that much uncertainty still necessarily exists concerning their intimate organization. Their locomotive apparatus most frequently consists of fringes of vibratile cilia variously disposed, the movements of which are most probably dependent upon the existence of a peculiar vital tissue distinct from muscle. In many species, e. g. the *Proteus (Amæba diffluens)*, the contractions of the body are extensive, so that even the outward form of the animalcule is perpetually changing, and some, the *Vorticellæ*, are attached to highly irritable pedicles of exquisite tenuity, that may be straightened or suddenly thrown into close spiral coils by some inherent power, the nature of which is as yet quite incomprehensible. In some, as for instance *Chilodon uncinatus*, moveable hooks are found to be appended to the surface of the animalcule, and some (*Nassula*) are provided with a peculiar dental apparatus, consisting of a minute cylinder of horny filaments; nevertheless no appearance of muscular or nervous fibre has as yet been detected even in the largest and most conspicuous species.

The Acalephæ next claim our notice as members of the Acrite division of the animal creation, and in every point of their economy they strictly conform to the general characters belonging to this type of organization. (See Acrita.) Their bodies are soft, pellucid, and gelatinous, without any trace of muscular fibre being perceptible in their composition; their digestive canals are excavated in the parenchyma of the body, not contained in any abdominal cavity, and the canals through which nutriment is conveyed to different parts of the system are entirely devoid of proper external coats; neither, as we believe, do nerves exist in any of the class, although, as we are well aware, two eminent observers have entertained a contrary opinion. Professor Grant,* in his account of the anatomy of *Cydippe pileus*, describes a double ring of nervous fibre as surrounding one end of the alimentary canal of that beautiful little Acaleph, and has even figured ganglia distributed at intervals upon these circular cords, from which secondary nerves are described as emanating. Such a circumstance as the existence of nerves and ganglia in an animal confessedly acrite, and presenting no traces of that type of structure which, in all other cases, invariably accompanies so elevated a condition of the nervous system, from its very singularity was well calculated to attract the notice of the physiologist, and we are ourselves quite satisfied that the distinguished professor has been led into error upon this point, most probably from having mistaken the circular canals, described by Delle Chiaje and others, as surrounding the oral extremity of the Beroes, and which are indeed frequently filled with an opaline fluid, for nervous fibre.†

* Vide Transact. of the Zoological Society of London, vol. i. and the figure at p. 109, vol. i. of this work.

† At the Birmingham meeting of the British Association, during a very interesting discussion upon this point, it was agreed by Mr. Forbes and Mr. Thompson, whose qualifications for such re-

Professor Ehrenberg has more recently announced that he had detected a nervous filament encircling the margin of the disc in one of the pulmonigrade Acalephæ, and connecting the red spots, which he is pleased, as we think without sufficient reason, to call *eyes*, with each other. Such a nervous system would, at least, be anomalous; and, notwithstanding the justly high reputation of the eminent professor of Berlin, we cannot but think that the interests of physiology require us to pause before we assent to the views of Professor Ehrenberg, as relates to the nature of the filament in question.

In the *Sterelmintha* or parenchymatous Entozoa of Cuvier, the same acrite condition, both of the nervous and muscular systems, is still observable in the lower forms belonging to this group of internal parasites, which being, for the most part, in their natural situations either enclosed in cells or closely imbedded in the substance of the viscera of other animals, could not be expected to have any power of locomotion conferred upon them; their bodies are, therefore, in the simplest species (such as the Hydatids, *Cysticerci*) mere membranous bags of homogeneous texture, and without a trace of fibre in their composition: their powers of moving are proportionately feeble, and are limited in fact to slight contractions, which are but indistinctly perceptible on the application of stimuli to the surface of the living animal.

In the Tape-worms (*Tæniæ*) the presence either of nerve or muscle is equally imperceptible, and the whole structure strictly conformable to the Acrite type. As, however, we mount higher in the scale of organization among these parasites, we again find how nearly succeeding types of structure are made to approximate, and even to a certain extent to become blended, as it were, with each other. In the Flukes (*Distoma*) and kindred genera, and in many of the Acanthocephalous Sterelmintha, although their structure is evidently parenchymatous, the skin, without presenting any decided appearance of muscular fibre, becomes more coriaceous and contractile, and at the same time nervous filaments become dubiously perceptible: a transition is obviously in progress, and thus we are gradually introduced to another and a more elevated series of animals.

The Nematoneura, as is obvious from every part of their economy, are gifted with higher attributes, and permitted to enjoy a more extended intercourse with external objects than any creatures comprehended under the preceding division. They are no longer rooted to one spot or imprisoned in enclosed cavities, but, on the contrary, are for the most part erratic in their habits, and in many of them the locomotive system is so efficiently constructed that their movements, exhibiting considerable activity and energy, argue the possession of distinct and precisely arranged muscles, and display such combination and consentaneous action of different parts of the body cooperating to produce a given result, that the existence of an intercommunication throughout the system by means of nerves might readily be predicated, even had not anatomy revealed to us that such animals actually possess a nervous apparatus. It would seem indeed to be clearly indicated by the physiological relations that exist between the two systems, that the possession of muscular fibre arranged in distinct fasciculi involves, as a matter of course, the co-existence of nervous threads, whereby the actions of distinct and distant muscles may be associated for the attainment of a common object; and accordingly we find that these two important additions to the animal economy make their appearance simultaneously. No large ganglionic masses are as yet developed of sufficient importance to be regarded as constituting a common sensorium, to which the perceptions derived from external senses must be referred, and from whence mandates of volition can be supposed to emanate. Senses, therefore, that is, localized and special senses, cannot as yet be given; the traces of individuality are but feebly recognizable; the vital powers are still, to a great extent, diffused throughout the different tissues of the body, and not collected and concentrated, as in animals possessed of brains, that is, of centralized and dominant aggregations of neurine; and, as a consequence of this important circumstance, some of the most striking characters common to the Zoophytes still linger in this division of creation; the radiated form is yet extensively met with, multiplication by mechanical division of the body is still, to a certain extent, possible, and severed portions of the body are found to be reproduced by growth from the mutilated part.

The Cœlelmintha or cavitary intestinal worms, living in the interior of other animals, differ in so many points from the Acrite Entozoa, that Cuvier, although in the Règne Animal he was content to group them together in the same class, was obliged to separate them into two distinct orders, calling the Sterelmintha "*intestinaux parenchymateux*," while the more highly organized are designated "*intestinaux cavitaires*." The Cœlelmintha, in fact, are organized in accordance with quite a different type of structure, as must be at once evident upon the slightest comparison between them. The digestive apparatus is now no longer composed of tubes excavated out of the general mass of the body, and presenting no outlet for the escape of egesta, but a distinct alimentary canal now makes its appearance, suspended in a capacious abdominal cavity, wherein, moreover, are lodged the male and female organs of generation, which in the Cœlelmintha are generally found in different individuals. The parietes of the body are in these worms obviously muscular, and are composed of contractile fibres arranged in superposed strata and affecting different directions. Towards the exterior of the body they are disposed longitudinally, but the inner layers assume a circular or spiral

searches are well known, that, although they had examined several hundred specimens of the Beroe in question, for the purpose of ascertaining this important fact, their endeavours to detect the nervous system referred to had been entirely unsuccessful.

arrangement; such a disposition providing for the extension or shortening or lateral inflexions of the worm, and enabling the animals so constructed to move about with facility in the cavities wherein they reside.

Nevertheless, at this, its first appearance in the animal series, muscular fibre has not as yet attained to the perfection of structure that it offers in the higher classes. The fibres are as yet indistinct, soft, and gelatinous; they appear to be deficient in fibrin; neither do they, when examined with the microscope, present the transverse striæ that are so characteristic of the muscular tissue in a more advanced condition. The little fascicles are, moreover, extremely short, and run but a little distance before they disappear, and are succeeded by others. Their whole appearance, in fact, is that of muscle in a rudimentary condition, and very accurately resembles the nascent muscular tissue when it first becomes apparent in the embryo of the vertebrate animal. The nervous system accompanying this condition of the muscles is extremely simple; a delicate ring surrounds the commencement of the œsophagus, by which, perhaps, the muscles of the mouth are associated during the act of imbibing nourishment, and prolonged from this ring are two long and thread-like nerves, one running along the dorsal and the other along the ventral aspect of the body, and passing quite from one extremity to the other, but without any perceptible ganglionic enlargements in their course.* Having, therefore, no brains or central masses to which perceptions could be referred, localized organs of sense are likewise wanting in all the Cœlelmintha. The Bryozoa which, while naturalists were ignorant of their more complicated organization, were, until a recent period, confounded with the Polyps, are, from their entire structure, very justly entitled to a much higher position in the scale of animals, and undoubtedly belong to the Nematoneurose type. These little beings inhabit transparent cells of very elaborate and delicate construction, from the mouth of which they protrude the anterior portion of their bodies when in search of food. Although from their general appearance the Bryozoa might easily be, and in fact have been until recently, erroneously regarded as Polyps, the differences between the two classes are exceedingly striking and important. The Bryozoa, instead of having the tentacula that surround the oral aperture quite simple and filamentary, as the Polyps have, are furnished with ciliated tentacula, and from the rapid ciliary movement which is incessantly going on, while the arms are expanded, strong currents are formed in the surrounding water, all of which impinging upon the oral orifice bring to the mouth such nutritive materials as are necessary for the support of the creature. The digestive apparatus is no longer a closed sacculus, as in the Polyps, but, on the contrary, presents a very elaborate structure, consisting of a gizzard, stomach, and distinct intestinal canal, terminated by an anal aperture, though which the fæces are ejected; and, moreover, the whole of the digestive viscera float loosely in a visceral cavity wherein they are suspended. In addition to this, the mouth of the cell occupied by the Bryozoon is defended by a most delicate and complicated opercular apparatus, requiring a very perfect set of muscles to perform all the required movements connected with the protrusion and retraction of the body, so that there is abundant reason for separating the animals in question from the Acrite Zoophytes.

As relates to their muscular system, rudimentary in its development as it must still necessarily be, many circumstances of great interest have been brought to light by the patient investigations of Dr. Arthur Farre, to whose valuable memoir* we are indebted for the following particulars, which we give at some length, more especially as they will serve not only to elucidate this part of our subject, but to correct several important errors that have been promulgated relative to the Rotifera, an important class of animals next to be noticed, of very analogous structure.

For the purpose of drawing the protruded Bryozoon into its retreat two distinct sets of muscles are provided, one set acting upon the *animal* and the other upon the flexible operculum that closes the cell. The muscles for the retraction of the *animal* are contained in the visceral cavity, and consist of two bundles of delicate thread-like cords, the one set arising from the bottom of the cell to be inserted about the base of the stomach, the other also arising from the bottom of the cell and passing up free by the sides of the pharynx to be inserted around the line of junction between this organ and the tentacula.

The muscles provided for the retraction of the operculum consist of six flattened bundles of fibres, which act upon the flexible portion of the cell and a delicate circle of setæ placed around its orifice. It is at once evident therefore that the muscular system in the Bryozoa is capable of great precision of action, and the fasciculi are most accurately adjusted. Nevertheless if the intimate structure of this form of muscle be investigated, it is found not to have attained to full perfection. "It would appear," says Dr. Arthur Farre, "as if muscular fibre were here reduced to its simplest condition. The filaments are totally disconnected, and are arranged one above the other in a single series. They pass straight and parallel from their origin to their insertion, and have a uniform diameter throughout their course, except that each filament generally presents a small knot upon its centre, which is most apparent when it is in a state of contraction, at which time the whole filament also is obviously thicker than when relaxed. The filaments have a watery

* The dorsal nervous cord of the Ascaris, first described by Cloquet, (Anatomie des vers intestinaux,) seems to have been overlooked by the learned writer of the article "Animal Kingdom," who has arranged the Entozoa as being diploneurose animals.

* Dr. A. Farre, on the structure of Ciliobrachiate Polypi. Phil. Trans. part 2 for 1837.

transparency and smooth surface, and under the highest powers of the microscope present neither an appearance of cross markings nor of a linear arrangement of globules." Besides the retractor muscles in the Bryozoa there likewise exists a muscular membrane which lines the cell, and forms the parietes of the body, in which fibres are distinctly apparent, running transversely: these by their contraction compressing the visceral cavity and the fluid which it contains will tend to elongate the body of the Bryozoon, and assist in effecting its protrusion; although, as Dr. Farre supposes, this process is principally accomplished by the cooperation of the alimentary canal, which has the power of straightening itself from the sigmoid flexure, into which it is thrown when the animal is retracted.

The condition of the nervous system in the Bryozoa has not been as yet made out, a circumstance at which no one will be surprised who considers the extreme difficulty of microscopic researches concerning the structure of animals so minute as these; but from the close affinity that there decidedly is between these animals and the Rotifera, there can be little doubt that a similar arrangement exists in both.

In the Rotifera or Wheel Animalcules, the nervous system, according to Ehrenberg, consists of several filaments communicating with minute ganglia dispersed in different parts of the body, although without any obvious arrangement or symmetrical disposition, so that the muscular apparatus in these beautiful animals presents itself in a very perfect state of developement. The ciliated organs around the mouth, which are apparently the representatives of the ciliated arms in the Bryozoa, are retracted by a special set of muscles derived from the interior of the membrane that lines the shell and circumscribes the visceral cavity, and the antagonists to these are the delicate parietes of the visceral cavity itself, which acting upon the fluid therein contained, causes the extrusion of the ciliated lobes, whenever the wheel-like organs are required to be put in motion.*

But besides the muscular bands, that, in the Rotifera, are appropriated to the protrusion and retraction of the wheel-bearing organs, others are connected with a peculiar prehensile apparatus placed at the hinder extremity of the body, and forming an instrument of very great importance in the economy of these creatures. It consists of a prehensile forceps, the blades of which are worked by distinct muscles; and by the assistance of this organ the action of the wheel-like cilia is at once changed from that of a locomotive power into a means of procuring and seizing food. If these forceps are not employed, the apparently rotatory organs propel the little animal rapidly through the water; but does it choose to take hold of some foreign body by means of its forceps, and thus anchor itself in a given spot, the use of the wheels is entirely changed, their rotation merely producing currents or rather a powerful whirlpool in the water, which sucks from a distance every thing within its influence, and thus brings food into the mouth.

The next class of animals, the Epizoa, present us with a beautiful series of gradations of development, clearly demonstrating the inseparable relation that must exist between the nervous and locomotive systems. The Epizoa seem, indeed, to be the osculant group interposed between the Intestinal worms and the Articulated classes, and exhibit in a permanent condition the progressively improving external articulated limbs, which are only permitted to attain their full development in higher races of the animal creation. The Epizoa, like the Cœlelmintha, are parasitic in their habits, living, however, upon the external surface, and not in the interior of other animals. They are principally found fixed to the eyes, the skin, the gills, or even the inside of the mouth of fishes, or to the branchial organs of various forms of aquatic animals, from which they suck the materials necessary for their support, and at the same time are freely exposed to the influences of the surrounding medium for the purpose of respiration. In the humblest of these parasites the structure of the body is scarcely superior to that of many Cœlelmintha, suckers and prehensile organs placed in the vicinity of the mouth being their only means of adhering to the surface upon which they live; but in the *Lerneans* the first appearance of outward limbs begins to be perceptible, not as yet recognisable as legs or locomotive agents, but not the less on that account the first rude sproutings of members that are to be by degrees perfected in more highly privileged genera. Some of these Lerneans, indeed, present most grotesque shapes, and almost exactly resemble the embryos of Vertebrate animals at the period when the first buddings of limbs begin to project from the sides of the body. This resemblance, indeed, is far more real than it would at first appear, inasmuch as there is a parallelism to be established between the permanent condition of the Lernean and the transitory state of the embryo at the corresponding period of its development that is strictly physiological. The condition of the nervous system in them both is precisely similar, exhibiting in both cases the nematoneurose type; the same rudimentary condition of the muscular system is consequently equally met with in the embryo and in the Lernean, but as the nervous system in the former is rapidly advancing to a more exalted state of development, so do the limbs and the muscles appertaining to them improve in the same ratio.

In the higher genera of Epizoa minute ganglia exist in connexion with the nervous filaments, and in such the limbs are of course more exactly formed and begin to sketch out

* It seems more than probable that the tranverse muscular fibres that occur in the parietal membrane of the Rotifera have been mistaken by Ehrenberg for vascular canals, described by that observer as emanating from a dorsal vessel; such at least is the opinion of Dr. Arthur Farre in the memoir above referred to, an opinion which quite coincides with the result of our own observations upon this subject.

as it were the limbs of Crustaceans and other Articulata.

The study of the muscular system in the extensive class ECHINODERMATA, the last of the nematoneurose division of the animal world, is invested with considerable interest on account of the very different kinds of locomotive apparatus that successively make their appearance; for as the outward form of these elaborately constructed creatures changes through all the phases represented by the *Encrinite*, the *Starfishes*, the *Echinus*, the *Holothuria*, and the worm-like *Siponculus*, the muscles successively assume a different arrangement.

The *Encrinite* in its outward form might be mistaken for a polyp, the jointed calcareous stem whereby it is fixed to the rock, the body and rays around the mouth, as well as the appendages to the stem, being all in their essential structure exactly comparable to those cortical polyps, that have an internal jointed calcareous basis of support. The numerous pieces that compose the skeleton of the Encrinite are all invested with a living contractile crust, whereby, in fact, they were secreted, and which forms the bond that connects them together. The living crust that covers the Encrinite can scarcely, indeed, as yet be looked upon as being muscular, so soft and acrite does its composition appear to be; nevertheless in these Echinoderms it seems to be the only moving power employed, and by its slow contractions bends the arms, or rays, or stem in any given direction.

In the long-armed Starfishes, such as the *Comatulæ*, *Gorgonocephali*, and *Ophiuri*, the slender and flexible rays around the body are in like manner covered with a living contracting skin, more dense and coriaceous than that of the Encrinite, but still presenting very dubious appearances of muscular fibre, whereby the movements of the rays are effected. The rays themselves constitute the instruments of progression, and by their aid these Polyp-like creatures crawl at the bottom of the sea, or by entwining them around the sea-weed that covers the rocks climb in search of food.

In *Asterias* and kindred forms the exterior of the body is still encrusted with the same contractile covering, and can be bent to a certain extent; but in these short-armed Starfishes the rays have become so short and devoid of flexibility that they can no longer be useful for the purposes of locomotion: an additional muscular apparatus is therefore now conferred in the extraordinary system of protrusible suckers, that become the chief agents in walking, or in seizing prey.

As we advance from the *Asteridæ* we find that the rays at length totally disappear: the body assumes a pentagonal form *(Palmipes)*, then circular *(Scutella)*, and at last is enclosed in an ovoid or globular shell, as in *Echinus*, *Cidaris*, &c. In these spherical Echinoderms the external soft and living crust that still covers the exterior of the shell presents obvious claims to muscularity, more especially where it passes on to the articulated spines that are attached to the surface of the shell and now become the principal means of progression. The suckers, however, that formed the only locomotive organs in the *Asteridæ* still are met with in the *Echinidæ*,—these and the spines constituting an apparatus for locomotion, which, for its complexity, is unparalleled in the animal creation. In the Echinidæ, moreover, a strangely constructed set of dental organs are developed, and for these likewise special muscles are appointed, for a description of which the reader is referred elsewhere. (See ECHINODERMATA.)

In the *Holothuridæ* the shell of the Echinus is no longer secreted, and the living integument itself constitutes the whole parietes of the body, which now becomes quite soft and flexible, clearly commencing that transition which is to connect the Echinodermata with the Annulose division of the animal kingdom. The suckers of the last family are, however, still persistent and form the principal means of moving from place to place. The texture of the fleshy skin of the Holothuria is dense and coriaceous, and strong bands of muscular fibre arranged in five divisions pass in a longitudinal direction, from one end of the body to the other, between which circular and transverse fasciculi are distinctly perceptible. Imbedded in the muscular walls that enclose the visceral sac of the Holothuridæ, delicate nervous filaments are to be detected passing along the body from end to end, and most probably these are connected together by a circular filament surrounding the œsophagus. Ganglia, if they exist at all, have, from their minute size, hitherto escaped observation; and, as might be expected from such a condition of the nervous system, the muscular contractions of the fibrous integument, although associated through the medium of the nerves, and consequently far stronger and more energetic than in the lower asteroid Echinoderms, are still almost entirely uncontrolled by the influence of volition; nay, so remarkably is this the case, that in most species of Holothuria, upon the application of the slightest stimulus to the exterior of the body, or even by simply taking them out of the water in which they live, such violent and general contractions of the whole integument are excited that the intestines and other viscera are forced extensively through the anal orifice, and it is almost impossible for the anatomist to procure a specimen of these creatures without finding it more or less spoiled from this circumstance.

Lastly, in the *Siponculi* the vermiform appearance is completely established, the longitudinal and circular muscles that bound the visceral cavity are strongly and distinctly developed, the complicated apparatus of foot-like suckers has disappeared, minute ganglia are visible towards the anterior end of the body, and we arrive at the annulose condition, that characterizes the next great division of the animal creation, which now offers itself to our contemplation.

HOMOGANGLIATA (Owen).—The third great natural group of living beings consists of creatures having the exterior of their bodies divided into rings or segments arranged behind each other in a longitudinal series, and generally furnished with lateral appendages of different kinds symmetrically disposed, which are subservient to many and very various purposes. The nervous system, moreover, throughout the entire range of this extensive series assumes a new and constant arrangement in itself, quite sufficient to characterize this sub-kingdom of animated nature, and with the different modifications of this portion of their economy are intimately connected the progressive changes observable in the structure and habits of the different classes included therein.

In the simplest conceivable condition under which a Homogangliate animal could exist, and doubtless among the lowest of the red-blooded worms and most imperfect forms of insect larvæ such a condition might be pointed out, the body would consist of a long succession of similar rings, each of which would contain an appropriate nervous apparatus consisting of a pair of ganglia symmetrically disposed on each side of the mesian line, from which nerves proceed for the innervation of the segment in which the brains or ganglia were placed. These ganglia in each segment communicate with each other and likewise with the pairs that precede and follow them by inter-communicating nervous filaments, and thus the entire series of individual brains or ganglia is united into one system made up of as many pairs as there would be rings entering into the composition of the body. There is, however, a remarkable difference between the anterior pair of ganglia and those placed in the succeeding segments. The first pair is invariably situated *above* the œsophagus on its dorsal aspect, while all the rest are arranged *beneath* the alimentary canal along the ventral region of the animal, so that the nervous cords that join the first and second pairs of ganglia embrace the œsophageal tube. The *supra-æsophageal* pair of brains invariably communicates with the instruments of the senses whenever such exist, and therefore is very justly comparable to the *encephalon* of higher animals; while the succeeding chain of sub-œsophageal ganglia animate the muscles of the different segments of the body, and may therefore be looked upon with great reason as representing the spinal cord of the Vertebrata.

But while the ganglia either of the head or of the ventral cord are thus numerous, as we have supposed them to be, in the lowest worm, they are as yet by far too small and devoid of energy in such a dispersed condition to correspond with organs connected with the higher senses, or even to wield muscles of sufficient power to support the weight of the body raised on articulated limbs. Therefore, before senses can be given or active limbs bestowed, a process of concentration must be gone through, the encephalic masses must be enlarged and thus rendered more perfect, the ganglionic centres that influence muscular movements reduced in number and made proportionately more energetic, and exactly in the ratio in which this improvement is effected in the nervous system, do the muscles become by degrees stronger and more efficient, and the limbs appended to the body more active and useful as locomotive agents. This, however, will be best exemplified by a rapid survey of the principal classes that compose the division of animals we are now considering.

In the lowest Annelidans, as for example the *Gordius* or hair-worm, so impotent are the minute ganglia bestowed, that even the rings upon the exterior of the body are scarcely indicated, and not the least vestiges either of limbs, tentacula, or eyes are to be detected. In the *Leeches* even, although the number of ganglia is in them considerably diminished, and rings of the body more strongly marked, external limbs cannot as yet be given, their place being supplied by the suctorial discs of the head and tail; nevertheless, even in these aquatic Annelides, the encephalic masses are sufficiently advanced to permit organs of vision to be granted, and accordingly for the first time in the animal series (as far as our own belief goes) are real eyes met with. The muscular system in these humble worms consists exclusively of the contractile walls of the body, the fibres of which are arranged in three strata, superposed one upon the other, and pass in different directions, one stratum being composed of longitudinal, another of obliquely spiral, and another of annular fibres surrounding the body of the animal; but these are sufficient for progression, all the movements of contraction, elongation, or flexure of the body being provided for by this simple arrangement.

In the *Nereis*, *Aphrodite*, and other erratic worms, external appendages become developed from the lateral aspects of the different segments, in the shape of bundles of setæ, moved by muscles appropriated to each set, and these constitute the first rudiments of locomotive limbs. The senses are at the same time improved in their condition, tentacula or feelers are found appended to the head, and the eyes become larger and more conspicuous, although still presenting the form of simple specks or ocelli.

In the Myriapoda the limbs become articulated, and of sufficient strength to permit of a terrestrial existence, each one of the numerous legs having a distinct set of muscles appropriated to its movements, in addition to the muscular apparatus, whereby the segments of the as yet flexible and elongated body are endowed with motion, and which of course represent the strata of the muscular covering of the Leech, strengthened and endowed with the capability of more precise action, in proportion as the cuticular skeleton has become more dense and distinctly jointed. Antennæ are, moreover, now placed upon the head resembling those of Insects, no doubt constituting organs of sense of a similar nature, and the eyes in Scolopendræ are found to be very distinct and perfectly organized, but still only ocelli resembling the simple eyes of Insects.

In the admirably constructed class of Insects, creatures adapted to an aerial existence, and consequently requiring the utmost exertion of muscular power to sustain their bodies in the air, the muscular system of the locomotive articulated appendages, the legs and wings, must undergo a still further improvement, and the means whereby this is accomplished are sufficiently manifest. The nervous ganglia are accumulated into a few large and powerful centres of innervation; the rings of the body, to which the locomotive organs are attached, are dilated and strengthened in proportion to the force of the muscles placed within, and constitute three thoracic rings of such firmness and inflexibility that they may well be looked upon as forming a distinct division of the exo-skeleton, and give rise to the distinction laid down by entomologists betweeen the head, the thoracic, and the abdominal segments that enter into the composition of an insect's body. But the same concentration of the nervous system, which permits an Insect to possess the extraordinary powers of flight with which it is gifted, allows by the increased perfection given to the brain, the possession of elaborately constructed senses. The eyes assume a complexity of structure that is truly wonderful, the sense of touch attains extreme delicacy, and indubitably the means of smelling, of tasting, and of hearing are now conferred, however incapable we may be of pointing out the mode in which they are exercised; nay, it is extremely probable that capabilities of perception of which we can form no idea, are bestowed upon the Insect races commensurate with the activity of their movements and the wide range of duties they are appointed to perform.

During the metamorphosis to which Insects are subject, that is to say during the advancement of these creatures from an embryo condition to their mature or perfect state, changes are constantly in progress, both in the nature and arrangement of the locomotive organs, and of course as these changes are effected, the entire disposition and even the vital properties of the muscular system appropriated to their movements undergo a considerable modification. The larvæ of many genera have externally the appearance of the simplest worm, being provided with not even any vestiges of the locomotive apparatus that subsequently is to be developed: even the rings or segments of the body are entirely soft, the cuticular covering being of extreme tenuity, and the tegumentary muscles, as a natural consequence, proportionally rudimentary in their structure. In such larvæ the nervous system exhibits the lowest condition found among the apodous Annelidans, and the eyes and external senses are, if they exist at all, of the humblest possible character. This is the case, for example, in the maggots of many Dipterous and Hymenopterous Insects.

In others, as for instance in the caterpillars of the Lepidoptera, the locomotive powers are of a slightly ameliorated description: the larva possesses a distinct head, and to the succeeding segments, rudely constructed limbs named *legs*, and others bearing still less resemblance to the locomotive members of the future insect, to which the name of *pro-legs* has been appropriated, are the only instruments of progression. Even in the most perfect larvæ, as in those of the aquatic Beetles, the form is elongated and resembles that of an Annelidan; the legs are comparatively feeble and of small size, and simple ocelli replace the compound eyes that afterwards become developed in the perfect Insect.

During the progress of the metamorphosis, the nervous system within is undergoing a process of concentration precisely comparable to that which has been noticed in advancing from the lower to the higher classes of ARTICULATA. The ganglia coalesce and become less numerous, the encephalic pair attain a higher development, and as this is accomplished the legs and wings of the mature being sprout from the sides of the segments appropriated to sustain them, enclosed in and defended by cases of cuticle temporarily provided, which constitute the covering of the pupa or chrysalis, until at length, the aggregation of the previously separated ganglia being completed and the brain perfected to the extent required, the pupa-case is thrown off, the newly-formed limbs expand, and the insect, with its newly-acquired limbs, possesses an additional system of muscles, which have been developed with their growth, and only arrive at their full state of perfection when the body has ceased to grow, and the generative system, having attained its complete proportions, proclaims the animal mature and able to propagate its species.

The addition of wings, indeed, to the body of flying insects would seem to be a provision specially connected with the distribution of the progeny to which they are to give birth, and all the phenomena connected with their development and that of the muscular apparatus provided for their movements to have relation to this great and closing act of the insect's existence. The period of time during which these animals live in their imperfect or wingless state, during which many of them have important offices assigned to them, constitutes, in most cases, by far the longest portion of their lives, and some aquatic larvæ, indeed, reside for months or even years in the water under their immature or wingless form, which perish in a few hours after they have been gifted with the means of aerial locomotion. Had they never been furnished with wings, it is abundantly evident that the species of such insects could never have been dispersed beyond the precincts of the pond or the ditch in which the parent had passed her existence, but the brief space allowed them to enjoy life in the winged condition is sufficient for the achievement of the great object in view, and the *Ephemeron* and the little *Gnat*, while they appear to be only sporting out their evening's life amid the sunbeams, are, in fact, disseminating their offspring through different localities.

The next class of HOMOGANGLIATE animals comprises the ARACHNIDANS, the *Scorpions* and the *Spiders*, animals visibly intended to be destroyers, appointed to keep within due limits the different races of the Insect world, and by assisting in the great work of destruction that is on all sides in progress against them, to prevent their fertility from becoming prejudicial to the other members of the animal creation. The tyrant must necessarily be stronger and more sagacious than the victims intended to be subdued, and accordingly, in the Arachnida, the great law that has hitherto been our guide in tracing the development of the muscular system is carried out one step further. The coalescence of the nervous ganglia and consequent concentration of the skeleton is found in these creatures to be more conspicuous than even among the Insects themselves: even the head and thorax, which in the last class were distinct from each other, now become fused into one piece, forming the *cephalo-thorax* of the creatures under consideration. The limbs and the jaws are thus rendered stronger and more formidable, and the muscles whereby they are wielded attain the fullest development permitted amongst articulated animals. Among the Crustacea forming the last class of this important sub-kingdom of creation, we find a series of aquatic Articulata running parallel as relates to the condition of their muscular system with the terrestrial Articulata, and exhibiting precisely the same relations between the state of concentration of the nervous system, and the degree of efficiency conferred upon their locomotive apparatus. The humblest forms of Crustaceans have all the segments of the body distinct and moveable, and, moreover, in their elongated shape resemble the larvæ of aquatic Insects. In these the articulated limbs appended to the different segments of the body are extremely feeble, and only adapted to natation; but proceeding upwards in the scale the locomotive members assume a more effective appearance, and the segments supporting them run together, and become consolidated. Whilst the muscles of the trunk preponderate in their development, as in the Shrimps and Macrourous Decapods, the limbs are of secondary importance as instruments of locomotion, and the largely developed tail forms a strong and powerful oar, a means of propulsion best fitted to their natatorial habits; but as we approach the shore and meet with Crustaceans, adapted to a littoral existence, the muscles of the trunk become diminished in importance in proportion as the legs acquire additional strength. The concentration of the segments of the trunk is carried out to the greatest possible extent in the Brachyurous Decapods, and the *Crabs* are thus enabled to leave the sea and prowl about upon the beach, or even to exchange an aquatic for a terrestrial existence; and, as in the case of the *Land Crabs*, to reside during a greater part of the year at a distance from their native element.

It is, however, interesting to observe that in the most highly organized of the Crustaceans, the *Brachyura*, the complete centralization of the body and nervous ganglia is effected, as in the case of Insects, in a slow and gradual manner, and that their muscular system undergoes a metamorphosis scarcely less remarkable than that observed among the Insects themselves. The *Crab* on first leaving the egg is almost in the condition of a long-tailed Shrimp, and the locomotive limbs scarcely to be recognised as being worthy of such a title, being not only rudimentary in their size but exclusively adapted for swimming; and it is only after several times casting its shell and passing through distinct gradations of form, that the muscles of the legs attain the preponderancy over those of the trunk and become strong enough for progression on land.

The fourth grand division of the animal kingdom, comprising the MOLLUSCA of Cuvier, is characterized by the dispersed condition of the nervous ganglia, which, throughout the extensive series of creatures constructed according to this type, are distributed without any symmetrical arrangement in different parts of the body, whence the Mollusca have been named by Professor Grant Cyclo-gangliata, and more recently by Professor Owen Hetero-gangliata, the latter term being, as we conceive, the preferable of the two. In the Mollusca the general outline of the body participates, more or less, in the want of symmetry that is so conspicuous in the disposition of the ganglia composing the nervous system, and the muscular apparatus does not exhibit that precision and regularity which is visible among all the Articulata. There is no longer, in fact, any frame-work, but when a shell is present, as, for example, in the *Snails* and kindred forms, both terrestrial and marine, it is only in those parts of the body that are protrusible from the testaceous covering that the tegument exhibits this decided muscularity, the mantle lining the shell being constantly thin and membranous.

But the most strongly developed part of the muscular covering of a gasteropod is the broad fleshy disc attached to the ventral surface of the body which constitutes the apparatus of locomotion, and gives the name conferred by zoologists upon the entire class. This disc, or *foot*, as it is likewise called, is entirely made up of contractile fibres, disposed in various directions, so as to confer all the capabilities of movement necessary for securing progression along the plane surfaces over which these sluggish animals are destined to crawl.

Having, as yet, no internal skeleton developed, and being equally destitute of any thing like an external articulated frame-work, it must be evident that if creatures of this description are to be provided with organs requiring to be moved by subordinate sets of muscles, seeing that there is no firm point of attachment to be found, as is the case among Insects or the Vertebrata, recourse must be had to a new plan, and accordingly few more remarkable deviations from what is generally met with in other animals can be pointed out than we meet with in the extensive class under consideration. The parts of the mouth, the tentacles, the eyes, and those parts of the male generative system needed for copulation, are in many instances so constructed that they may, when not in use, be completely retracted into the general cavity of the body and packed up amongst the viscera by means of a mechanism quite peculiar, and of which a particular account is elsewhere given. (See Gasteropoda.)

In the PTEROPOD MOLLUSCA, we likewise find the entire body enclosed in a muscular bag, forming what is called the visceral sac, but the locomotive organs present themselves under a different aspect. These consist of two muscular flaps or wings, appended to the opposite sides of the neck, which form, in fact, two oars or paddles, wherewith the little Pteropods row themselves about from place to place, or gambol gaily among the waves, which sometimes, in the northern oceans, swarm with countless multitudes of them. The lateral fins in question were regarded by Cuvier as being likewise subservient to respiration, an opinion, however, which Eschricht satisfactorily confutes. The latter writer, moreover, points out a little circumstance worth recording, namely, that the wings are not distinct and separate organs as at first they would appear, but that the muscles moving them pass continuously in a crucial direction through the neck of the animal from one wing to the opposite, so as to convert the whole apparatus into an exact representation of the double paddle used by the Greenlander, in rowing his *kajac*, or canoe, over the very seas frequented by the Pteropods, in such abundance.

In the Carnivorous CEPHALOPODA the muscular sac composing the body, the parietes of the head, and the long and flexible arms with their curiously constructed sucking cups appended, are all made up of variously disposed contractile fibres; but these are too fully and well described in another place to require more than a passing notice in this general survey. (See CEPHALOPODA.)

Arrived at the vertebrate division of the animal series, we at once find the moving powers assuming a complexity of arrangement and precision of action, proportional to the elaborate construction of the internal osseous, or cartilaginous skeleton, which now forms the framework of the body, and must be regarded as entering into the composition of several distinct systems of organs appointed to different offices, and physiologically independent of each other. Each of these systems, or sets of muscles, indeed, is developed for special purposes, and so far are they from progressively presenting themselves, in a gradually improving condition, as we rise from lower to more elevated orders of Vertebrate animals, that the physiologist must be prepared to expect every irregularity in this respect; important organs, or sets of organs, that in the lowest Vertebrata are found to be most elaborate and complex in their structure, are not unfrequently either wholly or partially obliterated, as we ascend the scale of animal life, and others equally important to the animals possessed of them, are only met with in certain races, that are endowed with peculiar habits or capabilities.

But, what is still more startling to the anatomist, who has confined his dissections to the examination of the muscular system as it exists in mature or complete animals, and has consequently been accustomed to describe as being permanent and invariable the origins and insertions of every muscle, that he meets with, the study of embryogeny reveals to the philosophical enquirer a series of changes in progress, as relates to the arrangement or even the existence of various parts of the animal economy, involving changes as remarkable, in all the muscular apparatus connected therewith.

In order, therefore, fully to lay before the reader, with as much brevity as perspicuity will allow, phenomena so important as those which next offer themselves to our notice, it will be advisable, first, to enumerate the principal systems of muscles that enter into the composition of a completely formed Vertebrate creature, premising that each may be but feebly developed in proportion to the rest, and many of them, indeed, absolutely wanting in a given animal, and afterwards to examine separately the varieties of arrangement met with in the animal series in relation to each, and likewise the metamorphoses that accompany embryonic development.

Without overburdening with detail this interesting enqniry, or unnecessarily multiplying divisions of the muscular apparatus, we shall content ourselves with grouping all the muscles of a Vertebrate animal, as belonging to one or other of the following systems, each of which will demand separate examination.

1. *Vertebral system*, muscles directly acting upon the spine and cranial vertebræ.

2. *Costal system*, muscles moving the ribs and parietes of the thorax and abdomen.

3. *Hyoid system*, muscles acting upon the os hyoides and branchial arches.

4. *Opercular system*, muscles moving the operculum of fishes.

5. *Muscles of the limbs.*

6. Muscles acting upon the *lower jaw* and serving for mastication.

7. *Tegumentary system*, muscles acting upon the skin and its appendages.

8. *Vocal system*, muscles of the voice.

9. *Diaphragm.*

10. *Lingual system.*

11. *Ocular system*, muscles moving the eyeball and its appendages.

12. *Aural system*, muscles acting upon the ossicles of hearing and moving the external ear.

13. *Nasal system*, muscles acting upon moveable parts of the nose.

14. *Generative system*, muscles attached to the apparatus of generation.

1. The muscular apparatus peculiarly appropriated to the movements of the vertebral chain of bones presents its maximum of developement in the osseous fishes, in which animals locomotion being principally accomplished by the lateral sweepings of the broadly expanded vertical tail, every arrangement has been made to increase the depth of the spinal column and to extend the surface presented by the superior and inferior spinous processes to the greatest possible degree, not only by lengthening inordinately those processes themselves, but likewise by appending to their extremities additional pieces derived apparently from the exo-skeleton. The muscles destined to act upon the flexible spine of the fish are propor-

tionate to the violence of the impulse required in moving the tail, and occupying the lateral regions of the body, extend quite from the head to the caudal fin, constituting almost the entire bulk of the animal, and possessing sufficient strength from their combined contractions to scull the fish through the water with surprising velocity, or even to enable the salmon to throw itself up the cataract, that bars its progress up the river, where it is commissioned to lay its eggs.

During the changes that accompany the developement of the tadpole, which by its metamorphosis into a frog is literally converted from the condition of a fish into that of a reptile, the transmutation observable in the condition of the muscles acting upon the spine are not less remarkable, than those witnessed in the vertebral column itself. Whilst in its tadpole state the frog is, as regards its powers of locomotion, strictly a fish, and rows itself about entirely by the movements of its expanded vertical tail exactly as fishes do, but as the limbs of the reptile gradually make their appearance the lateral muscles of the spine that previously formed the bulk of the creature are absorbed and disappear, the hitherto flexible and elongated vertebral column becomes short and but little gifted with motion, and its muscles in the same ratio grow feeble and unimportant.

In the other forms of Reptiles, as well as in Birds and Mammalia, the muscular system acting upon the vertebral chain presents great uniformity of character, the number and strength of the muscular fasciculi being exaggerated, or diminished in different regions in proportion as mobility is permitted, the movements of the spine being generally diminished, and trammelled in exactly the same ratio as the locomotive limbs become more perfect and efficient.

2. The costal muscles form a system apart, quite independent of those connected with the vertebral column, and exactly keeping pace with the developement of the skeleton of the thorax. In Fishes a thoracic cavity cannot be said to exist, inasmuch as the ribs that enclose the viscera seem rather processes fixed to the spine, in order to give a greater extent of surface for the attachment of muscles destined to act upon the tail, than properly the representatives of the costal elements of the skeleton; neither do ribs exist in the tadpole, or even in the perfect frog. Even in those Batrachia that are most gifted in this particular, minute cornicula appended to the apices of the transverse processes of the vertebræ are the only rudiments of a costal system of bones, and these muscles are vainly looked for.

In the Tortoises and Turtles likewise, although both *vertebral* and *sternal* ribs are present, and so hugely developed that they constitute the great bulk of the carapax covering these strange reptiles, such is the immobility of the dorsal shield, and so securely are the ribs conjoined by suture, that any muscular apparatus destined to act upon them would have been obviously superfluous.

In Serpents, however, the case is widely different; for in these lithe and limbless creatures the ribs are made to serve as most important locomotive agents, and their movements must be proportionably free. Dorsal ribs only are here met with, but these being now moveably articulated to the sides of the spinal column, and moreover acting at their opposite extremity upon the ventral scuta, perform the duties of internal legs, and being continued in an unbroken series from the very atlas nearly to the termination of the tail, it is not difficult to imagine the numbers and complexity of the additional muscles now provided, to wield organs so numerous and important.

In Lizards and in Birds the thorax assumes its most complete state of developement, and exhibits both dorsal and sternal ribs articulated to each other and capable of extensive movements; muscles are therefore given to act upon both the dorsal and the sternal series.

Lastly, in the mammiferous races the anterior costal bones are once more removed, their place being occupied by elastic cartilages, the resiliency of which to some extent antagonizes those muscles which act upon the moveable portions of the thorax.

The *sternum*, or rather the sternal system of bones, although frequently found to enter largely into the composition of a thoracic cavity, seems rather to be in relation with the anterior extremity, and the muscles derived from it principally subservient to the motions of those limbs. Thus in the frog and toad we have a largely developed sternum without either ribs or thorax; and in the case of Birds, the strict correspondence between the condition of the sternum and the powers of flight is most strikingly exemplified.

3. Perhaps the most interesting lesson to be derived from such a survey of the muscular system of vertebrate animals as this, is taught by an examination of the hyoid apparatus, and of the muscles connected with it, in the different members of the vertebrate series, and also during the different phases of embryonic developement, in any of the air-breathing or more elevated classes. It is in Fishes that this part of the skeleton exhibits the greatest complexity of structure, and forms a most elaborate framework of branchial arches, destined to support the gills, which some writers have been tempted erroneously to consider identical with the thorax of the air-breathing races. The branchial or hyoid organs are in fact substitutes for the thoracic or pulmonary portion of the skeleton, and in exact proportion as the latter becomes more complete, and better adapted to aerial respiration, does the former shrink in its dimensions and become simplified by the obliteration of successive portions, which previously entered into its composition, and a consequent remodelling, as it were, of the muscles connected therewith. Thus during the metamorphosis of the tadpole, the branchial arches that before were largely developed, are progressively found to disappear as the lungs assume their office, and the whole hyoid system of bones and muscles changed so as to become adapted to the performance of totally different functions.

The permanent or adult condition of the

hyoid apparatus likewise undergoes a progressive simplification as we examine it in the more elevated forms of Vertebrata. Thus, in the bird it still consists of elements, that in the mammiferous animal may be dispensed with. The cornua, the last remnants of the branchial arches, are still largely developed in many quadrupeds, and in fact it is only when we arrive at the human species that we see the pieces composing the hyoid portion of the skeleton reduced to their simplest condition, and the muscles appended thereto correspondently reduced in their number and modified as regards the functions they perform.

4. The muscles that act upon the opercular openings in Fishes are, of course, peculiar to animals possessed of a branchial respiratory system.

5. The muscles of the limbs exhibit perhaps greater varieties than any others belonging to the animal economy, their existence and relative size being entirely dependent upon the kind of progression conferred on any given race or family of the vertebrate creation. It would seem indeed that an inverse proportion always exists between the condition of this system of muscles and those that act upon the trunk—the large developement of the one set rendering the other of secondary importance. Thus in the generality of the osseous Fishes the enormous bulk of the lateral muscles of the trunk renders any great strength of limb unnecessary, and the muscles moving the pectoral and ventral fins, the representatives of the arms and legs, are proportionately small and feeble; but in the Plagiostome Cartilaginous Fishes, the *Skates* and *Rays*, the conditions are precisely reversed; the muscles of the trunk shrink into comparative insignificance, and the enormously developed hands, which here form the great bulk of the body, moved as they are by muscles of corresponding power, form the great agents in locomotion, and by their vigorous flappings raise these creatures from the bottom of the sea, their usual resting-place.

The phenomena attendant upon the growth of the limbs in Amphibious Reptiles beautifully exemplify the same circumstances. In the *Lepido-siren*, that possesses still the form and the scales of a fish, although it breathes both with gills and lungs, the legs or fins, for it is difficult to say to which appellation they are best entitled, are of the simplest possible structure, each consisting but of a simple, tapering stem, so flexible and feeble that it can scarcely be deemed at all useful for the purposes of locomotion.

In the *Siren lacertina* we have still the long and flexible body of an eel, the tail obviously forming the chief, or, indeed, the only effective agent in progression. Nevertheless, seeing that this Amphibian being possessed of lungs can breathe the air, the first sproutings of legs are here manifest. Two rudimentary limbs corresponding with the anterior pair of other reptiles, and terminated by four extremely imperfect toes, are appended to a feeble scapulary apparatus, and thus the Siren is allowed to raise its head at least out of the marsh where it resides, and obtain a supply of the atmospheric fluid.

The *Proteus* is, in form, almost as fish-like as the Siren, and its tail is still a strong and muscular oar; the limbs nevertheless are slightly more developed; and besides the imperfect anterior extremities, each of which is terminated by three toes, a rudimentary pelvis and pelvic extremity are now sketched out, the latter presenting two little toes, but hardly as yet sufficiently complete to be useful as locomotive organs.

Equally striking examples of the gradual developement of locomotive extremities are found in those reptiles whereby the transition is effected, between the Ophidian and Saurian types of structure; thus in the genus Anguis, as for example, in the common English blind-worm (*Anguis fragilis*), although externally it would appear to be as strictly apodous as the generality of other serpents, yet on stripping off the skin, these reptiles are found to possess the first rudiments of limbs, that are afterwards to be made efficient in more highly gifted genera; a little pelvis is distinctly discernible, imbedded in the muscles towards the hinder part of the body; and, in front, a sternum, scapula, and clavicle, may all be perceived hidden beneath the integument, although no traces of legs or feet are as yet to be detected.

In other serpents more nearly approximated to the quadrupedal Saurians, as in the genus named *Bimanes* (*Chirotes*, Cuv.) in addition to the scapulary apparatus, two short anterior extremities armed with toes, moved by tolerably complete muscles, are met with, whilst the hinder legs are wanting. In Bipes, on the contrary, it is the pelvic pair of legs that are developed, the place of the anterior being only indicated by the existence of the frame-work and muscles of the shoulder. Lastly, in the Saurians and Tortoises the quadrupedal type is fully adopted, and the muscles of the limbs assume an importance proportionate to the duties they have to perform.

Still more interesting is it to watch the daily growth of the muscles that make their appearance, as the legs of the Frog are slowly formed, budding, as it were, from the sides of the Tadpole, and vicariously taking the office of those, that previously constituted the locomotive apparatus; the vertebral system of muscles, whereby the tail of the aquatic animal is moved, being entirely obliterated as the limbs advance to maturity.

6. The masticatory muscles, or those connected with those movements of the lower jaw that are concerned in the preparation of food, present great uniformity of arrangement throughout all the Vertebral orders, and obviously constitute a distinct and isolated group, the development of which is in exact relation with that of the rest of the manducatory apparatus.

7. The tegumentary system of muscles, although only represented in the human body by a few detached and isolated remnants, constitutes among many of the lower animals a very important part of their economy, either

destined to act upon the skin itself or upon cuticular structures of very diversified shape, which are occasionally developed in different regions of the body, and not unfrequently appropriated to the performance of important duties. In those quadrupeds that have their backs covered with strong spines, such as the Echidna, the Porcupine, and the Hedgehog, the cutaneous muscles, usually named *panniculus carnosus*, are met with in their most complete form, since in these creatures every quill or spine is moved by muscular bands connected with its base, that serve to erect or depress it at pleasure. The crests and other moveable appendages to the skin met with among Birds, are equally furnished with the means of motion by strengthening particular parts of the muscular apparatus in question.

In *Reptiles*, on account of the nature of their corneous integument, the muscles of the skin are but slightly developed, or indeed most generally are not to be detected. But in *Fishes* they once more present themselves, under a novel and most important aspect. The azygos fins in these aquatic Vertebrata are, as is elsewhere shewn (vide PISCES), derivations from the exo-skeleton, and consequently all the slips of muscle, that act upon the individual rays of the dorsal, caudal, or anal fins, however anomalous their nature may appear without such a key to their real character, are obviously merely portions of the tegumentary system of muscles here elevated into an importance not witnessed in other animals, where the exo-skeleton is less decidedly appropriated to the purposes of locomotion.

8. The muscles whereby vocal sounds are modulated, are equally entitled to be looked upon as a distinct and superadded system only conferred upon certain races of Vertebrata, and that under very various conditions. In Fishes these muscles are of course absolutely wanting, and even amongst the air-breathing Reptiles they are so imperfectly developed as scarcely to be regarded as vocal organs. But in *Birds* and Mammalia they assume a higher form, and are variously located and more or less numerous in exact proportion as the voice is perfected. In Birds, indeed, the vocal muscles are principally placed at the thoracic extremity of the trachea, but in Quadrupeds and in Man, at the opposite end, the whole machinery being thus so completely altered that even analogies between the different sets of muscles are not easily pointed out.

9. The *diaphragm* is an apparatus exclusively conferred upon the Mammiferous Vertebrata, since in these only is the thoracic cavity separated from the abdomen by a muscular septum.

10. The muscles of the tongue must likewise be regarded as forming a distinct group, increasing in complexity and extent of motion, in proportion as the organ to which they belong assumes greater importance, either as an instrument for the prehension of food, or as an agent in mastication.

11. The ocular system of muscles may be divided into those which act on the eyeball, and those employed in moving the palpebral appendages. The former when complete consist of four *recti*, two *obliqui*, and the *choanoid* or suspensary muscle, which not unfrequently is distinctly divided into four. The *recti* are invariably met with and present few variations worthy of notice. The obliquus superior in Mammals passes through a pulley, which is not the case in other Vertebrata, while the *choanoid* muscle is principally met with in Quadrupeds.

The muscles of the eyelids are most perfectly developed in Birds, in which distinct muscles are appropriated to the movements of the upper and lower eyelid as well as to the nictitating membrane, which in the feathered races has a proper set of muscles appointed to draw it over the eye not met with in other classes.

12. The muscles of the auditory apparatus become fully developed only in the mammiferous ear, where four little muscles are invariably found connected with the ossicula auditus, as in the human subject. The muscles appointed for the movements of the external ear are, however, in many Quadrupeds much more numerous than in Man; in fact, in the human ear they merely exist, in a rudimentary condition.

13. The nasal apparatus has likewise a system of muscles of its own, although the instances in which it is met with in anything like a complete state of developement are comparatively rare. In Fishes, Reptiles, and Birds these muscles, indeed, can hardly be said to exist; and even in the generality of Mammals they are feeble and unimportant. It is only in the proboscidean species, that the nasal muscles assume their full complexity, and the trunk of the elephant is in modern times the only example, wherein the anatomist can contemplate them.

14. The muscles of the generative system are only found to exist, as a distinct set, in the Mammalia, as in these alone is the urethral canal complete, and a perfect ejaculatory apparatus given.

Thus, therefore, we may learn from this short survey, that so far from finding in the human frame the fullest and most elaborately constructed examples of the various divisions of the muscular system, or, in other words, a typical condition of that part of the animal economy, the human anatomist, in many instances, has only an opportunity of examining the vestiges or rudiments of organs, that in the lower animals attain to a far more complete developement.

(*T. Rymer Jones.*)

MYRIAPODA, (from the Greek μυριας, ten thousand, *i. e.* numerous, and πους, a foot,) the name of an important and highly interesting class of articulated animals, intermediate in their structure and appearance between the Annelidans and the Insecta, properly so called; approximating the former in the worm-like form of their bodies, which are composed of a great number of rings or segments, and likewise allied to the latter by the construction of their jointed locomotive legs; these, however, instead of being only six in number, as in the true Insects, are, in the Myriapoda, always at least twelve, and frequently extremely numerous, being appended to all the segments of the elongated body, whence the names "Centipedes" and "Millepedes," by which these creatures are commonly designated. All the members of the class are apterous; they exhibit externally a succession of cylindrical or compressed rings, each of which sustains one or more, frequently two pairs of jointed feet, all of very similar construction, being generally terminated by a single sharp claw. There is no consolidation of the anterior segments into a thorax resembling that of the Insecta, although many celebrated Entomologists are disposed to regard the three anterior rings as the representatives of the thoracic segments. Upon the head are placed two antennæ or feelers, which, in one large group, are short, stunted, and composed of seven articulations, whilst in others these organs are long and setaceous, presenting a much greater number of distinct joints. Compound or simple eyes, allied in their structure to those of Insects, are generally, but not always, present. The mouth is formidable, and, in many respects, resembles that of Insects, being furnished with strong mandibles, adapted to devour either animal or vegetable substances. All the species breathe air by means of lateral stigmata and tracheal tubes, a circumstance whereby they are at once distinguishable from the CRUSTACEA. Their jointed legs remove them from the ANNELIDA, while they differ from the Insecta in many important particulars, but more especially in the progressive growth of their bodies, by the production of new segments, and the development of additional locomotive limbs, the number of which increases with the age of the animal, while, on the contrary, in Insects, the segments that existed at birth are found to coalesce into a smaller number, and the prolegs of the larvæ become obliterated when the Insect attains its complete hexapod condition.

All the Myriapoda are terrestrial in their habits, lurking beneath stones or in the crevices of houses. Many of them inhabit decaying timber, or are found beneath the bark of trees, where they devour such vegetable substances as are adapted to their support; or, in the case of the more highly organized species, wage war against other animals, upon which they feed.

The classification of the Myriapoda has hitherto been and still is exceedingly imperfect and unsatisfactory, apparently in consequence of their very wide distribution and the general similarity of their appearance. Our countryman, Dr. Leach, in his zoological miscellany, was one of the first who gave a general arrangement of these animals, which was adopted by Latreille; but he appears only to have examined the European species. In Griffiths' Translation of Cuvier's Animal Kingdom, Mr. J. E. Gray, of the British Museum, gave the figures of some exotic genera; but of these the Editor left the descriptions very imperfect, and only made slight references to them in the explanations of the plates. Since that time Dr. J. F. Brandt published a monograph of the *Myriapoda chilognatha*,* in which he pointed out several new genera and re-named many, previously established by Mr. Gray. More recently M. P. Gervais has published his studies on Myriapods,† consisting of a revision of the class and a list of the species, but having overlooked the slight notes given of Mr. Gray's genera, has in one or two instances been led into error. Under these circumstances it is, with very great satisfaction, that we are able, by the permission of Mr. Gray, who has kindly placed his manuscript at our disposal, to lay before our readers the following review of the entire class.

Order I. *CHILOGNATHA*, Latr.
(*Julus*, Linn.)

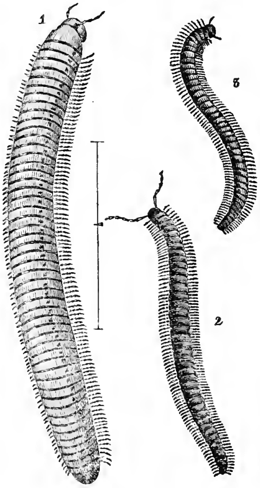
Antennæ seven jointed; rings of the body furnished with two pairs of legs.

Fam. 1. JULIDÆ. Body cylindrical, smooth, rolling up into a spiral form and composed of many joints. Each segment formed of three imbricated parts, the upper part covering the body and sides of the abdomen. Antennæ short, thick. Eyes many in a group.

Gen. 1. JULUS. (*Fig*. 304, 1, 2, 3.)

2d, 3d, 4th, and 5th joint of antenna elongated, attenuated; 2d longest, 5th and 6th longer than the rest.

Fig. 304.



Julus.

* Bull. Soc. Imp. Moscow.

† Annales des Sciences Naturelles for 1837.

Gen. 2. SPHÆROBOLUS. Brandt.
2d, 3d, 4th, and 5th joint of antenna short, roundish, equal; the 2d rather longer than the rest, the 5th and 6th nearly equal.

Gen. 3. SPEROSTREPTUS. Brandt.
Lower lip with a semilunar pit in the middle and without any tubercles. Eyes many, in lunate tubercles.

Gen. 4. SPEROPŒUS. Brandt.
Lower lip with two transverse oblong tubercles separated by a transverse groove.

Gen. 5. SPEROCYCLISTUS. Brandt.
Lower lip flat, with tubercles placed in an impression in the centre of its base.

Fam. 2. CRASPEDOSOMADÆ.
Body cylindrical (striated), consisting of many joints, each formed by a single piece, antennæ slender. Legs 48 pairs or more. Eyes many, in a linear series or triangular patch.

Gen. 1. CRASPEDOSOMA. Leach.
Body elongate, depressed. Rings with a compressed lateral edge. Eyes in a triangular patch.

Gen. 2. CYLINDROSOMA. Gray.
Body elongate, quite cylindrical, with very indistinct longitudinal striæ. Eyes in a small oblong, kidney-shaped patch.

Gen. 3. REASIA. Gray.
Body subcylindrical, striated longitudinally. Eyes in a nearly linear patch.

Gen. 4. CAMBALA. Gray. *Platyulus*, Gervaise.
Body rather depressed. Eyes in a double line on each side of the back of the head.

Fam. 3. POLYDESMIDÆ.
Legs 31 pairs. Eyes none or only single tubercles, situated just on the outer side of the tentacles.

Gen. 1. POLYDESMUS. Latr.
Body elongate, depressed: rings slightly edged at the sides, forming an interrupted margin. Antennæ with rather long joints.

Gen. 2. FONTARIA. Gray.
Like Polydesmus, but the margin of the body is rude, and forms a continuous edge.

Gen. 3. STENONIA. Gray.
The body slender, the rings subquadrate, with toothed extended lateral edges.

Gen. 4. STOSATEA. Gray.
Body slender, subcylindrical; the lateral margin forming a very slight ridge.

Fig. 305.

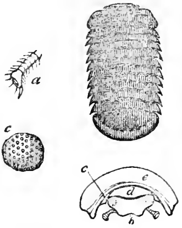
Fam. 4. GLOMERIDÆ.
Body depressed; rings 11; semilunar. Eyes 8, placed in an arched line on each side of the head. Antennæ inserted on the upper front part of the head.

Gen. 1. GLOMERIS. Latr.
The first dorsal ring striated in the middle of the side. (*Fig.* 305.)

Gen. 2. LAMISCA. GRAY. *Glomeris, β.* Brandt.

Fam. 5. ZEPHRONIADÆ.
Body depressed; rings 12; semilunar. Eyes many in a circular group. Antennæ on the side of the head. (*Fig.* 306. *a b c d.*)

Fig. 306.



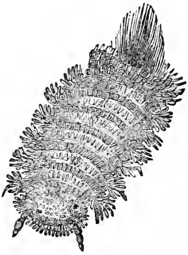
Gen. 1. ZEPHRONIA. Gray. *Sphæropocus.* Brandt.
Antennæ 6-jointed, penultimate joints short, last largest, oblong, rounded at the tip. (*Fig.* 306.)

Gen. 2. SPHÆROTHERIA. Brandt. *Zephronia*, part. Gervais.
Antenna 7-jointed, 6th joint nearly oblong, last joint smallest, truncate at the tip.

Fam. 6. POLYXENIDÆ.
Body depressed; rings 6; soft, semilunar, with a tuft of scales on each side; feet 12-12. Eyes many in a group.

Gen. 1. POLYXENUS. Latr. (*Fig.* 307.)

Fig. 307.



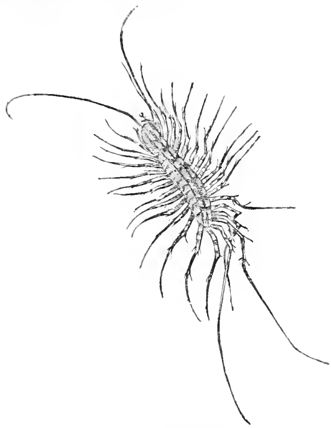
Polyxenus lagurus.

Order II. *CHILOPODA.* Latr.
Antennæ of 14 joints or more. Segments of the body flattened, each bearing only one pair of feet.

Fam. 1. SCUTIGERIDÆ.
Antennæ filiform, very long. Legs very long. Eyes reticulate.

Gen. 1. SCUTIGERA. Lamarck.
Feet 15 pairs or more. (*Fig.* 308, *Scutigera livida.*)

Fig. 308.



Scutigera livida.

Fam. 2. SCOLOPENDRIDÆ.

Antennæ tapering, moniliform, moderate. Legs numerous, moderate. Eyes numerous in groups, or wanting.

Gen. 1. LITHOBIUS.

Segments of the body 17, imbricate. Eyes many, gregarious. Antennæ 20 to 40 jointed. (*Fig.* 309, *Lithobius forficatus.*)

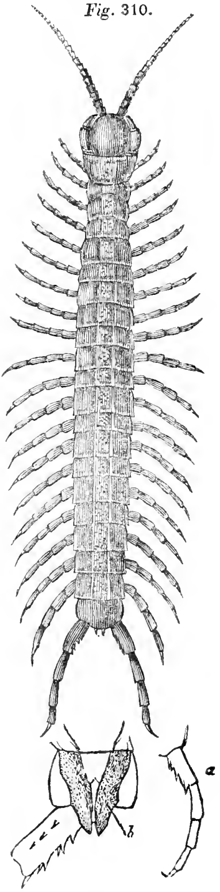
Lithobius.

Gen. 2. SCOLOPENDRA.

Eyes 4–4. Stemmatiform. Antennæ setaceous, 17 or 20 jointed. Body of 23 depressed rings. Feet 21 pairs, hinder longest, with the first joint spinulose (*Fig.* 310.)

Fig. 310.



Gen. 3. CRYPTOPS.

Eyes inconspicuous. Antennæ setaceous, 17 jointed. Feet 21 pairs, hinder longest, not spinous.

Gen. 4. STRIGAMIA. Gray. (*Geophilus.*)

Eyes none. Antennæ 14 jointed, moniliform, rather elongate. Body linear, depressed. Feet very numerous, fifty pairs or more.

The whole body of a Myriapod consists of a succession of similar rings or segments of various form and consistency, the number of which would seem to be constant in the mature or adult animal, but subject to important and very remarkable varieties during the progress of its growth. In the lower forms, such as Julus (*fig.* 304), the texture of the segments is hard, crustaceous, and brittle; but in the Scolopendroid races, the rings are flattened and covered above and below with tough and coriaceous scutæ. In all the Chilopoda each segment supports only a single pair of ambulatory legs, which resemble in many respects those of insects, but terminate invariably in a simple claw. In the Chilognatha, on the contrary, with the exception of a few of the most anterior, and likewise of the terminal or anal segments, each ring has two pairs of feet attached to its under surface, consisting apparently of two half segments conjoined; and this view of their composition is further strengthened by the fact, that a deep transverse indentation or groove is always visible upon the dorsal surface, dividing the otherwise apparently single ring into an anterior and a posterior moiety, to each of which is fixed a pair of short and very feeble legs, composed of several distinct articulations. The three first segments in Julus form exceptions, however, to this arrangement, each of these supporting only a single pair of ambulatory feet, and these segments have been supposed by some authors to represent the thoracic segments of the true insects. The seventh ring, likewise, in the female, has one pair deficient, they being replaced by the orifices leading to the sexual organs. The anal and penultimate segments are completely apodal in the Julidæ, whilst, on the contrary, in some of the Chilognatha, the size of the locomotive limbs increases progressively as we approach the caudal extremity, the last segment supporting the longest pair, which are directed backwards, so as to have in some measure the appearance of a furcate tail.

In the *Scolopendridæ* (*Chilopoda*, Latr.), a family which embraces those forms of Myriapoda that are most nearly allied to Insects, we have a race of carnivorous Myriapods, possessed of strong and active limbs, varying in number in different genera from fifteen to twenty-one pairs, by the aid of which they can run with considerable rapidity, and are able, owing to the flexibility of their long and jointed bodies, to wind their way with facility among the lurking places of Insects, against which they carry on an unrelenting warfare. All of them are found carefully to avoid the light, and generally to frequent damp situations, more especially where decaying animal or vegetable substances abound. They lurk, therefore, under stones or pieces of old wood, or are met with beneath the bark of trees, localities which from their structure they are peculiarly adapted to occupy.

In the following account of the anatomy of these creatures we shall select the Scolopendræ, properly so called, for particular description, as being the largest and, consequently, most commonly met with in our collections, noticing, however, as we proceed, such peculiarities as may be worthy of notice in other genera.

The Scolopendræ have their bodies composed of twenty-one segments exclusive of the head, to each of which is attached a pair of jointed legs. The segments are all of them more or less quadrilateral in their shape, their transverse diameter being generally the longest, but their size is very variable and irregular. The whole body is depressed, each segment, consisting of a dorsal and a ventral plate of soft but corneous consistency, formed by a thickening of the cuticle in those regions of the body, while the sides to which the legs are appended, and where, moreover, the respiratory spiracles are situated, are soft and of a coriaceous texture.

The legs are all five-jointed and terminated in a simple sharp horny claw: those appended to the segments in the neighbourhood of the head are comparatively small, but as they approximate the hinder part of the body they increase in size and strength, the last pair being turned backwards so as scarcely to be useful as locomotive agents.

The head, and more especially the parts entering into the construction of the oral apparatus of these Myriapoda, present many difficult inquiries to the scientific entomologist, who would attempt to identify them with apparently corresponding structures met with in the organization of the mouth of insects, and accordingly we are not at all surprised to find that no two authors agree as to the names that are most applicable to the different pieces belonging to this portion of their economy. The Myriapoda, be it remembered, are obviously an osculant or transition group allied at once to the Annelidans, to the Insecta, to the Arachnidans, and to the Crustacea. It is by no means surprising, therefore, that, in the construction of almost every part of their bodies, we find an organization intermediate between these important divisions of articulated animals, as we shall again and again have occasion to notice. But, perhaps, in no part of their economy is this intermediate structure better exemplified than in the mouth of the Scolopendra, to the different portions of which all writers appear to have given names rather in conformity with their own preconceptions than with any real affinities that have been pointed out, or any general view of the real nature of such appendages. With all respect for the opinions of preceding writers, we shall, on this account, endeavour, in the following description, to avoid as much as possible technicalities peculiar to the orismology of any particular branch of zoological science.

The head of a Scolopendra, or that portion of the creature which supports the instruments of sensation and the organs employed for the prehension of food, appears, when viewed superficially, to consist of two segments, one a circular shield-like plate, constituting the real head, that exists only upon the dorsal aspect of the body, in which are inserted the antennæ, and which, moreover, contains the eyes and overlaps the greater number of the pieces belonging to the mouth. The second segment, by far the larger and the stronger of the two, and, in fact, from the density of its corneous envelope, the strongest segment of the whole body, is entirely devoted to the support and movement of a pair of sharp bi-articulate and hooked fangs resembling jaws, that move transversely like the (so-called) mandibles of a Spider, but which are in reality only modifications of the ambulatory feet converted into instruments for killing prey, each being perforated near its sharp termination with a long oval slit, through which venom is said to be instilled into the wound inflicted by this formidable weapon.

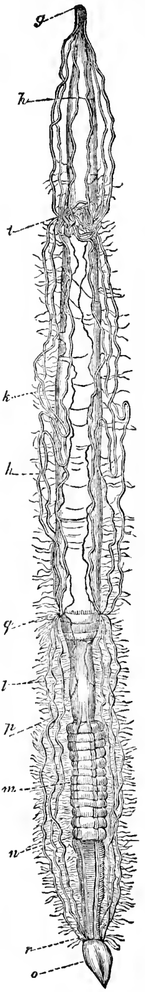
The head properly so called, namely the circular shield-like plate seen upon the dorsal surface at the anterior extremity of the body, although apparently consisting of a simple horny disc, is doubtless composed of several segments conjoined superiorly; indeed, these are completely confused, and inferiorly are too soft and membranous to be distinguished, except by the presence of those articulated appendages, which, although forming parts of the mouth, are still merely repetitions of the jointed legs affixed to the other segments of the body. Thus the most superficial plate, with its articulated appendage, the *labium* and *labial palpus* of entomologists, is but an incomplete ventral scutum, with its articulated limb in a rudimentary condition as compared with those of the body, and is even armed with a distinct claw, as are the locomotive legs. In like manner the second pair, the *maxillæ* of authors, are legs but one step further removed from their normal form, but not more so than are the poison-fangs already described. In the third pair or mandibles we have a leg reduced to its terminal claw, and that is broad and serrated so as to become useful in manducation. Lastly, the corneous and serrated piece (the *labrum*) seems to be the last vestige left of limbs of this description, the two horny remnants of legs having become consolidated with each other and with the dorsal head-plate, so as to form the anterior boundary of the mouth.

Alimentary canal.—The alimentary canal in all the Myriapoda is of extremely simple construction, and both in its form and general arrangement, very nearly resembles that of the larvæ of Lepidopterous Insects. In Julus terrestris (*fig.* 311) the œsophagus (*h*) is seen to be of considerable capacity, in accordance with the nature of the coarse food upon which these vegetable-eating species live. The stomach is long and bowel-like, extending from the termination of the œsophagus to the insertion of the hepatic vessels. To this succeeds a wide and sacculated colon, which passes directly to the anal segment of the body, where it terminates.

In the Scolopendroid genera the same conformation of the alimentary apparatus is met with, the stomach and intestine passing straight from the mouth to the anus without any peculiarities of structure worthy of notice.

In *Lithobius forficatus*, which we may take as a specimen of one of the Chilopod Myriapoda, a very similar arrangement exists; the œsophagus, which is proportionately narrow, ends in a simple stomachal enlargement of an oblong shape, and this terminates in a straight bowel, the point of separation between the one and the other being only indicated by the entrance of the biliary vessels.

Fig. 311.

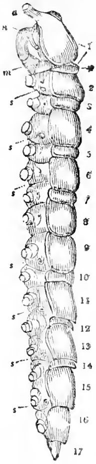


The glands connected with the alimentary apparatus closely resemble those of the insect larva. Two convoluted salivary tubes are seen folded up at the sides of the œsophagus, where their convolutions are intervolved into a species of ravel (*fig.* 311, *i*) with the origins of the hepatic vessels (*h*), which latter, after a tortuous course, are inserted, as in Insects, at the termination of the stomachal portion of the digestive tube.

Respiratory System.—The Myriapoda respire in the same manner as Insects by means of lateral spiracles and tracheal tubes. The spiracular orifices are, in the Scolopendridæ, very conspicuous, as, for example, in Lithobius, (*fig.* 312,) where the corneous lips of the apertures leading to the tracheæ (*s*, *s*, *s*, *s*) are seen situated behind the origins of the legs, upon the sides of the 2d, 4th, 6th, 9th, 11th, 13th, and 15th segments, occurring upon the alternate segments, except in the case of the 8th, where there is one missed. The tracheæ derived from these spiracles pass inwards to be disbributed upon all the viscera, ramifying in every part of the body, and thus conveying air throughout the system. In structure these air-vessels exactly resemble those of true Insects, and are equally characterized by the existence of a spiral fibre in their interior, whereby they are always kept permeable.

Circulatory system.—In the nature of their circulatory apparatus the Myriapoda are closely related to the Insects properly so called. A long dorsal vessel passes from the tail towards the head along the mesial line of the body. The sides of this vessel, on clearing away the fat which surrounds it on all sides, are seen to be perforated at intervals with numerous valvular orifices, through which the circulating fluid gains free admission from the general cavity of the body, and by the undulatory contractions of the dorsal heart thus constructed is forced forward toward the head. Arrived in the neighbourhood of the œsophagus, the dorsal heart is seen to give off several vessels, and according to the opinion of Mr. Newport and Mr. Lord,* there is reason to suppose that a vascular system more complete than has as yet been proved to exist in any of the true Insects may be pointed out in this region of the body. The dorsal vessel itself, when examined under a microscope, is distinctly muscular, being formed of circular flat bands that surround the cavity of the tube, so that doubtless the action of this heart, in the larger species at least, is sufficiently energetic.

Fig. 312.

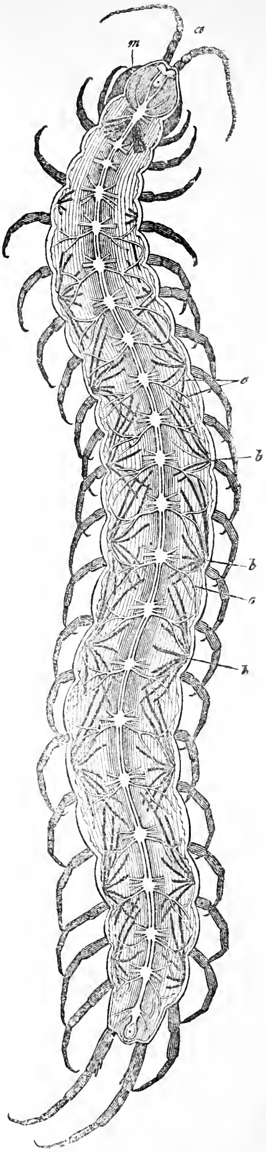


Foramina repugnatoria.—These are a series of orifices which in the Julidæ are seen upon the lateral aspect of every segment of the body, and communicate with as many minute membranous sacculi placed within the body. These sacculi, both from their position and relations, forcibly remind us of the series of respiratory sacs met with in the Leech and other air-breathing Annelidans, but in Julus they are supposed to be merely organs of secretion from which some offensive fluid is poured for the protection of the animal.

Nervous system.—The nervous system of the Myriapoda, as in all the Articulata, exhibits a double series of ganglia connected by cords of inter-communication. The supra-œsophageal ganglion, situated within the cephalic segment of the body as relates to its development, seems to hold a place intermediate between that of the Annelida and of Insects, or perhaps more strictly speaking, corresponds with the larva condition of the latter. The ventral chain of ganglia is numerous in proportion to the number of segments which enter into the composition of the body, their number decreasing as the locomotive limbs over which they preside become more fully developed and capable of more vigorous action. Thus in Julus and Geophilus, where the limbs are extremely numerous and feeble, the ganglia in their number and small size approximate the condition they exhibit in the Nereis or more elevated Annelides, but in Scolopendra (*fig.* 313) the more powerful limbs and stronger muscles required by their carnivorous habits demand greater developement of the centres of the nervous system.

* Vide Med. Gazette for 1837.

Fig. 313.



Senses.—In the structure of their organs of sensation likewise, the Myriapoda so nearly resemble Insect larvæ that little can be said concerning them in addition to what the reader will find elsewhere stated. (See articles ANNELIDA, CRUSTACEA, ARACHNIDA, INSECTA.) The *antennæ* upon the head, which are invariably two in number, correspond in all essential circumstances with those met with in Insects, and doubtless perform the same functions. The *eyes* when present, which is not the case in all the genera, exhibit the form of simple ocelli congregated upon the head, and arranged in lines or triangular patches; but in no case do they exhibit the appearance of a really compound eye, such as is possessed by the generality of Insects in their perfect state. With respect to the other senses, touch, taste, and smell, but little is known except by conjecture, and presuming them to exist we can only suppose them to be conferred in the same manner as in the real Insect.

Generative system.—A remarkable difference exists between the Chilognatha and the Scolopendroid Centipedes with respect to the position of the organs of generation. In the former the external openings, both of the male and female genitals, are situated near the anterior extremity of the body, as is the case among the Annelida; whilst in the Chilopodous genera, which exhibit a higher grade of organization, the generative apertures are found in the caudal segment as in the Insects.

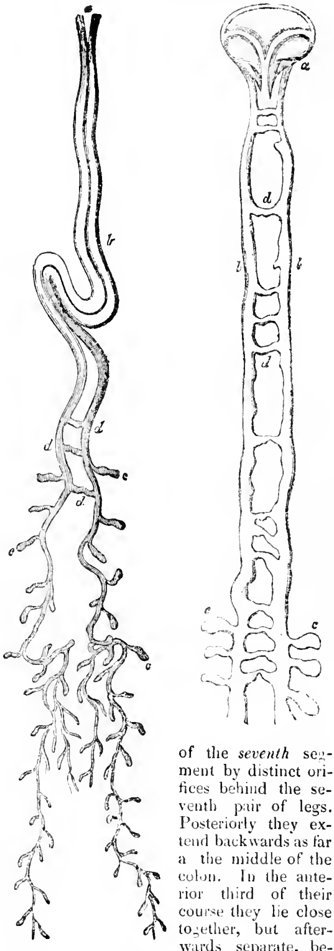
In *Lithobius* the structure of these parts is in both sexes very simple. In the male there are three long and convoluted secreting tubes resembling the simplest form of the testis in Insects, wherein, doubtless, the seminal fluid is elaborated. These are united at their terminations so as to form a kind of common receptacle, from which two tubes proceed to the root of the intromittent organ, at which point they are joined by four smaller auxiliary vessels, which seem to take their origin in masses of fatty substance. The penis is a horny cylindrical tube that can be protruded from beneath a valvular plate which covers the anal orifice (*fig.* 309, *o*).

The female apparatus consists of a single sacculated ovarium, occupying the mesian line of the body. From this proceeds a narrow excretory duct, which, however, prior to its termination beneath the anal segment becomes considerably dilated into a cavity that has been improperly named *uterus*. Here it receives two sets of supplementary vessels, the one a pair of wide cœca, the other composed of four convoluted vessels apparently destined to secrete some additional covering to the eggs before their extrusion. The female generative orifice, situated in the anal segment, is covered with a horny plate and furnished with a pair of small horny forceps calculated to assist in copulation.

The male generative organs of Scolopendra present a very peculiar structure; but these we have already described elsewhere (see GENERATION, ORGANS OF).

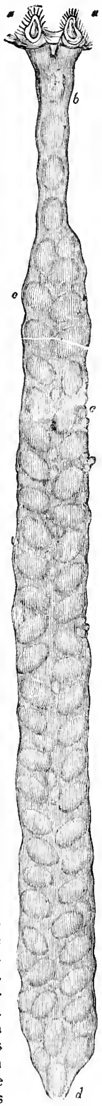
The male generative organs of Julus (*fig.* 314. A) are two elongated and partially convoluted tubes placed side by side beneath the alimentary canal immediately above the nervous system. The excretory ducts or terminations of these tubes run towards the *anterior* part of the body, where they terminate in two organs of intromission (*a*), which pass out at the under surface

A *Fig.* 314. B



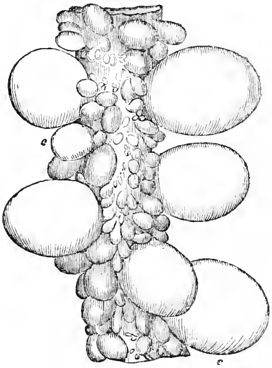
of the *seventh* segment by distinct orifices behind the seventh pair of legs. Posteriorly they extend backwards as far a the middle of the colon. In the anterior third of their course they lie close together, but afterwards separate, become smaller, and have developed from their sides at short distances a number of minute glandular cœca, or transparent vesicles (*c*), which doubtless constitute the secreting portions of the apparatus or proper testes of the animal. The two efferent ducts, whereby the secretion of these cœca is conveyed out of the body, inter-communicate freely by short transverse canals (*fig.* 13, *d d*), and from the sacculated appearance that they present towards their termination appear in some species to perform likewise the office of reservoirs for the seminal fluid. In a large African species Mr. Newport found the double organ of intromission to be prehensile (*fig.* 314, B, *a*), each part having the form of a distinct claw between the moveable joints, of which passes out the elongated half corneous penis. These parts are covered in anteriorly by a horny valve somewhat of a triangular form, and the whole occupies an oval space on the under surface of the seventh segment, corresponding to that usually occupied by the legs. "With regard to the product of secretion in these organs," observes Mr. Newport,* "I have never yet found any thing but a granulous fluid in the cœca, apparently similar to the granules in the higher animals from which Spermatozoa are produced, but this might have arisen from the immature recent specimens I was alone able to obtain. It would be interesting to ascertain whether these germs of Spermatozoa are produced in the cœca as there seems reason to believe, as we shall presently find that the ova in the female are secreted in sacs which appear to be analogous to these cœca in the male organs. I am inclined to think that the Spermatozoa are not developed until the granulous fluid has passed into the efferential ducts at the season of impregnation."

Fig. 315.



The female organs of the *Julidæ* (*fig.* 315) are described with equal minuteness in the paper above referred to, from which we extract the following exceedingly valuable observations, as nearly as possible in the words of Mr. Newport himself, to whom we are also indebted for the illustrative figures. In the female Julus, the organs of reproduction are as simple as those of the male. They consist of a single elongated bag or oviduct, covered on its exterior surface with a very great number of ovisacs or cœca of various sizes, each of which secretes but a single ovum. This oviduct extends backwards beneath the alimentary canal, from its double vaginal outlet (*a a*), which is situated in the fourth segment behind the second pair of legs, as far as the posterior part of the rectum close to the anus, where it ends in a *cul-de-sac* (*d*). It is most nearly in contact with the alimentary canal on its upper surface, but is separated from it by adipose tissue; in the pregnant female it is smooth, and distended with ova that have passed into it from the ovisacs, and are ready to be deposited immediately after intercourse with the male. The ova at the anal extremity, that is, at the commencement, of the duct are as perfect as those near the vaginal outlets. The oviduct contains within its cavity, at least from seventy to eighty of these perfect eggs awaiting impregnation, arranged in two or more irregular rows, and greatly distending its sides. In some of the larger species of the genus there are four and in others five rows of eggs, the number of which is much greater than in our native species. The ovisacs (*fig.* 315 and 316, *c c*)

Fig. 316.



are little sacculi, distributed thickly to the number of many hundreds over the whole exterior of the oviduct, from its posterior or cœcal extremity to within a short distance of its vaginal outlets. Each ovisac, whatever be its state of developement, contains but a single ovum, every part of which is produced in it, from the germinal vesicle in the most rudimentary form to the yelk, albuminous fluid, and shell. This fact deserves particular consideration. A large proportion of the ova in the ovisacs never arrive at maturity, but are retarded in their growth by the more rapid developement of others that are near them, so that on examining an oviduct partially distended with ova, the greater number of ovisacs in different states of developement, are at the sides and on the under-surface of the duct, in parts which correspond to the interstices between the fully developed eggs, that have passed into the oviduct, or are still forming on its exterior. One row of ovisacs usually exists on each side of the duct near its upper part, but most of the ovisacs in the course of developement are at its sides.

* Phil. Trans. for 1841.

The structure of the duct and of its numerous ovisacs is best seen in those specimens that have not yet arrived at maturity, or in those which have just deposited one laying of eggs. In these individuals the oviduct, to within a short distance of its division into two outlets, is studded with minute ovisacs, each filled with the rudiments of its minute ovum. Its general appearance in a female, that has recently deposited its eggs, is completely botruoidal, very like the ovary of Birds, some ova being always fully developed, and ready to pass into the oviduct, while others are in various stages of developement, many of which are imperceptible except with the aid of a powerful lens.

But the most remarkable condition of the female organs in the Julidæ is their double vaginal outlet, as in Crustacea, although the oviduct itself is a single tube until near its termination, where it is divided into two short canals, which from a slight opacity at their base, where they join the single duct, appear, when seen by transmitted light, to be separated from it by a valve or duplicature of the lining mucous membrane. The vaginal orifices are simply two nipple-shaped portions of the tegument, with somewhat oval apertures surrounded by a corneous ring, from which is developed a circle of minute hairs. They are situated on the under surface of the fourth segment of the body, and correspond in position to the insertion of the legs in the third segment.

Ova.—We have already seen from Mr. Newport's description of the female generative system of *Julus*, that the ova are formed in separate ovisacs, from which they issue completely constituted eggs, into the cavity of the ovarium or common duct, through which they are expelled from the body after impregnation; and we now proceed to lay before the reader the important results of the investigations of that distinguished anatomist relative to the structure of the ova themselves, and the progress of embryonic developement. The existence of the ovisacs in Julus as single isolated capsules on the exterior of the oviduct, in each of which a single egg is produced, is, Mr. Newport observes, a circumstance particularly favourable to a minute examination of the ovum in all its states, especially as ova are found at the same time in every stage of developement. The smallest *ovisacs* appeared like very minute glandiform bodies, developed, as it were, immediately from the structure of the duct itself, and in these the rudiments of the future egg had already begun to be produced. The smallest rudiments of eggs examined were of an elongated shape, and as yet not more than three, or at most four blood-globules in diameter. They appeared already to have distinct parietes, and to be filled with very minute graniform cells of a uniform size, slightly opaque, and of a yellow colour. The diameter of these cells, as nearly as could be ascertained by direct comparison, was equal to about one-third of that of a blood-globule. In the midst of these cells there was a larger but much more delicate structure of a circular form and equal in size to about two of the cells, but whether this was the *germinal vesicle* or its *macula* could not be determined. Other ovisacs twice the size of the foregoing were filled with similar contents, and from the opacity and yellow colour of the graniform cells, it was evident that they constituted the yelk in one of its earliest stages. At a later period both the yelk and its including vesicle are inclosed in a distinct membrane—the *membrana vitelli*, and before its escape into the oviduct all the parts of a perfect egg, namely, the *yelk*, the *germinal vesicle* with its *macula*, the *membrana vitelli*, the *albumen*, and likewise the *shell* lined by the *membrana externa* or *chorion*, are completely formed.

Evolution of the embryo.—The developement of the young Julus Mr. Newport divides into several distinct and well-marked periods, during each of which phenomena are presented of the utmost interest, both to the physiologist and in an entomological point of view.

The first period extends from the deposition of the egg to the gradual bursting of the shell, and exposure of the embryo within it, occupying the space of twenty-five entire days, during which the egg acquires a sensible increase of bulk.

On the nineteenth day there was a complete alteration in its form; it was more obtuse at both ends, and had become much larger, and the outline of the embryo, coiled up within the shell and nearly filling the whole interior, was very distinct, although, as yet, there were no rudiments of limbs or even of a division of the body into distinct segments. On the following day, the twentieth, the outline of the embryo was more apparent, and on its concave or ventral surface there were faint traces of a division of the body into six segments (*fig.* 317*).

Fig. 317.

Up to this period Mr. Newport was unable to detect any funis or umbilical cord attached to the embryo, although, in consequence of Rathke's observations in Crustacea, such a structure was particularly sought for, the whole body still appearing to be formed of cells of different sizes.

From this time the egg became every day larger until the *twenty-fifth* day, when it was greatly distended and began to assume a kidney-shaped appearance, and commenced bursting longitudinally in the median line of the dorsal surface, the back of the soft and perfectly white embryo gradually pressing through the opening.

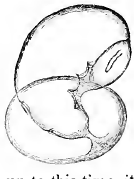
In the *second period of developement* the embryo is exposed to a new medium, and perhaps derives the means of its further growth from external sources, although it is still enveloped in the fœtal membranes and retains its connection with the shell.

The liberation of the embryo is a remarkably slow process as compared with the escape of other animals from the egg. In Mr. Newport's observations, from ten to twelve hours

* This and the succeeding figures are copied from Mr. Newport's paper, before quoted. The objects have been magnified twenty-five diameters.

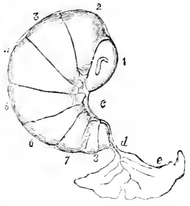
elapsed before the body of the young myriapod was so far liberated as to remain only partially enclosed between the two halves of the shell, as represented in *fig.* 318, being still attached to its interior by a pedicle or funis (*fig.* 319, *d*). So remarkable is its condition at this period that it strongly resembles the expansion of the germ in the seed of a plant, rather than the evolution of a living animal. The embryo is perfectly motionless, and the bursting of its shell appears to be effected not by any direct effort of its own, since, up to this time, it has acquired only the form and external semblance of a living animal; but, by the force of expansion of the growing body, the development of which being greatest along the dorsal or larger curvature, exerts, in consequence, a greater degree of force against the middle of the dorsal than the corresponding part of the ventral surface; the head and tail of the embryo acting as a fulcrum against the ventral surface only at the ends of the shell, and thus bending it into the kidney-shaped form it assumes, while the dorsal surface of the embryo is gradually pressed through the opening. From the comparative rapidity of its enlargement immediately after the shell is fissured, Mr. Newport observes, that it seems as if the stimulus given to it by exposure to a new medium, atmospheric air, were the great means of exciting its evolution.

Fig. 318.



The embryo is now formed of eight distinct segments (*fig.* 319), including the head, the ninth or anal segment being still indistinct. The head is more defined in its outline, and firmer in texture than other parts of the body, and is inflected against the under surface of the prothorax (2) or second egment, from which it is divided on the upper part by a deep transverse line: at its sides it exhibits a faint trace of the future antennæ. The four thoracic segments also exhibit on their ventral surface little nipple-shaped extensions, three of which on each side are the rudiments of future legs. When viewed from above, the body of the embryo appears compressed and wedge-shaped, its greatest diameter being in the second and third segments, while each succeeding segment is more and more contracted. Mr. Newport was unable at this period to detect any separate internal organs, the whole embryo being still a congeries of vesicles or cells, in the midst of which there seemed to be some faint traces of the commencement of an alimentary canal.

Fig. 319.



"At the end of the first day," continues Mr. Newport, "I carefully removed the embryo and shell into diluted spirits of wine, and, on examination beneath the microscope, found the body of the embryo covered with an exceedingly delicate cuticle, through which the cells it was formed of were distinctly visible. It was also completely enclosed in a smooth and perfectly transparent membrane (*fig.* 319, *c*), which seemed to contain a clear fluid, interposed between it and the embryo. This membrane I regard as the analogue of the *amnion*, the *vitelline* or investing membrane of the embryo in the higher animals, and identical with the *membrana vitelli*, before described, as the proper membrane of the yelk in the egg of Julus. It is a shut sac that completely invests the embryo, except at its funnel-shaped termination at the extremity of the body (*fig.* 319, *d*), where it is constricted, and together with another membrane (*e*), which in the unburst egg is external to this and lines the interior of the shell, assists to form the cord or proper funis (*d*).

"The funis enters the body of the embryo at the posterior part of the dorsal surface of the future penultimate segment, where the mucro or spine exists in the adult animal, and not at the dorsal surface of the thoracic region, as seen by Rathke in the Crustacea. The proper anal or terminal segment is, as yet, but imperfectly developed. In the funis (*d*), I also observed some exceedingly delicate structures that exhibited all the appearance of vessels. They seemed to enter the body by two sets, that were spread over and entirely lost in the membrane (*e*). Whether these were indeed vessels, or merely folds of the membrane I am not certain. The membrane (*e*) in which they appeared adheres closely to the shell and retains the embryo in connection with it by means of the funis. In the unburst egg, this is also a shut sac like the amnion, and forms the *membrana externa* or chorion (?), the second or outer investing membrane of the ovum lining the interior of the shell.

"The detection of these two investing membranes of the embryo in Myriapoda may," says Mr. Newport, "be regarded with some interest in reference to the analogies which they bear to similar structures in Vertebrata, since they shew the persistence of one universal law in the mode of development of the germ."

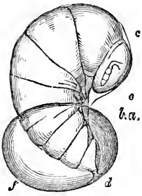
On the *third day* the embryo had considerably increased in size, but was still perfectly motionless and attached to the shell by the funis. This attachment continues for many days, during which the embryo remains partially protected by the two halves of the shell. When examined at this period in the recent state, all the parts of its body are still indistinct, but in specimens that have been for some time in spirits of wine, the divisions between the segments are well marked. The rudiments of the legs are more developed, but those of the second and third segments less than the fifth, so that not only at the bursting of its shell, as noticed by Savi, but also for several days afterwards the embryo is competely apodal, the future limbs existing only in a rudimentary state. Posteriorly to the fifth segment, the body is more soft and delicate, and the segments less clearly defined. This results from the circumstance that it is at this part of the body that the future new segments are to be produced.

On the *fourth day*, Mr. Newport first observed some faint traces of a single eye, or *ocellus*, on each side of the head. The embryo had now further increased in size, and the rudiments of its future legs had become larger and more obtuse, an appearance which the newly-formed limbs of the Articulata often exhibit previously to their further elongation. Traces of the formation of internal organs were now evident through the tegument at the posterior part of the body, and the funis was contracted as if about to separate. Internally the body was still formed of cells aggregated together, but differing more in size than at any previous period, as if they were becoming fused into separate tissues, and in the midst of them and closely surrounded on all sides was the newly-formed alimentary canal. The canal was now more opaque, and when pressed out of the body more firmly adhered together than any other internal structure, and was distinctly composed of an aggregation of very minute cells. Around the sides of the body muscular structure was also in the course of development, but as yet was exceedingly indistinct, insomuch that Mr. Newport could discover no perfect fibre, a fact that sufficiently accounts for the entire absence of spontaneous motion in the embryo up to this period.

A new process was now about to commence —the development of new segments. On the third day, as has been already stated, the posterior part of the body is less distinctly divided into segments than the anterior, the first five segments being most distinctly marked. The sixth and seventh are now more defined. It is in the membrane *f*, *fig*. 321, that connects the seventh with the eighth segment at the posterior margin of which last the funis (*d*) enters, and which segment is permanent as the *penultimate* throughout the life of the animal, that the formation of new segments is taking place. At this period it is only a little ill-defined space that unites the seventh and eighth segments into one mass, but in proportion as the anterior parts of the body become developed, this part is also enlarged, not as a single structure, but as a multiplication or repetition of separate similar structures.

On the *ninth day* the changes have advanced much further (*fig*. 320); not only have the future new segments become more distinct, but transverse depressions are also seen on the dorsal surface of the original segments, shewing their division into double ones, as in the perfect animal. The rudiments of the legs are now further developed, and their transparent distal extremities are seen through the investing membrane applied closely together and extended along the ventral surface of the body, as in the nymphs or pupæ of true Insects. The antennæ and ocelli are more apparent, and the embryo itself has increased at least one-third of its original dimensions. It is still attached by the funis to the shell, but this attachment is daily becoming more fragile, and is now separated by very slight causes. The embryo has thus continued to grow through nine succeeding days, since the bursting of its shell, without any visible means of nourishment, the nutriment supplied by the yelk having been exhausted before that occurrence. Hence it becomes a matter of inquiry from whence it now derives its means of growth? Whether it has already sufficient materials derived from the egg, and stored up within itself for its future development, or whether the external inclosing membrane may not still contribute to the function of nutrition by absorbing fluid condensed from the air of the humid locality in which it resides. The probability of this last supposition, says Mr. Newport, is somewhat countenanced by the fact that I have constantly observed the membranes of the embryo at this period covered with microscopic drops of fluid, but whether this is fluid condensed on the membranes from the atmosphere of the dwelling, or whether it results from the transudation of that which was contained in the amnion, remains for future inquiry.

Fig. 19.



Up to this period the embryo gives not the slightest evidence of spontaneous or voluntary motion. Internally it is still composed of cells of different sizes that are now in the course of producing muscular and other structures. In some parts of its body no arrangement of them seems as yet to have taken place, the cells being merely aggregated together. Cells of three very distinct sizes now exist. The diameter of the largest of these is nearly three times that of the second size, and the second again are nearly twice and a half the size of the smallest. The smallest sized cells fill up the interspaces between the others, and appear as if breaking down to form interstitial or cellular substance, while the second sized cells are arranged in rows to form particular structures.

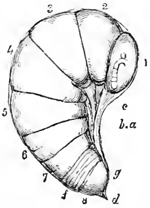
In the midst of these cells the alimentary canal is now nearly complete, but Mr. Newport was unable to observe its connexion with the funis. At its anal extremity it is a little dilated, and extends forward as a short straight intestine, the *rectum*, until it arrives at a part where a valve seems about to be formed. The diameter of the canal is there enlarged, and on its surface are three distinct longitudinal muscular bands. The so-called *hepatic vessels* also exist as distinct tubes inserted one on each side into the alimentary canal at the constricted or valve-like part above noticed. The canal is then continued forwards until it is again dilated into the proper stomach, and terminates or rather commences in a narrow œsophagus. It is much longer than the body of the embryo, being convoluted or folded upon itself in its lower portion, to adapt it to the changes that the body undergoes in the enlargement and elongation of its segments. It is not yet separated from the now forming structures by any distinct investment, either adipose or peritoneal, except only what belongs to itself; but is closely surrounded by cells of the second and third size.

On the *tenth day* the great circulatory or dorsal vessel was distinctly seen through the amnion and skin. This doubtless had existed much earlier, although not observed. It was exceedingly well marked, but Mr. Newport was as yet unable to detect any motion in it. The head of the embryo had now begun to assume the peculiar corneous appearance common to the larvæ of true insects; its body had much increased in size, and the amnion was still covered with microscopic drops of fluid.

On the *eleventh day* the head was more distinct, and the antennæ appeared at its sides like short crescent-shaped clubs, with their terminations directed forwards. Above them the single ocelli were distinctly seen. All the segments, posterior to the third, exhibited the transverse line that indicated the division into double segments, and the posterior segments were much increased in size.

On the morning of the *seventeenth day (fig.* 321) Mr. Newport found all the embryos ready to leave the amnion. Some of them were already detached from the shell; others were still connected to it. Their increase of bulk within the last few hours had been very great. The body was now more straightened, the head less inflected under the thorax, and the eye was a dark-coloured spot above and behind the antennæ. The segments of the body were divided by distinct reduplicatures of the proper tegument, and the legs folded side by side against the ventral surface were much further extended beneath the amnion (*b, a*). The transverse divisions of the first six segments strongly marked the original segments, and the amnion, now about to burst, was tightly extended over the dorsal surface, and by the elongation of the body was rendered more distinct on the ventral. The great increase in the length of the animal was mainly occasioned by the growth of the posterior segments, more especially those in the antepenultimate space, the proper germinal space or membrane (*f*), the faint divisions of which into new segments were now distinctly seen through the amnion. The seven anterior segments, including the head, were greatly enlarged, and the hitherto minute anal and penultimate segments (8, 9), in the first of which the remains of the funis (*d*) forms a rudimentary spine, had also become enlarged, and were now fast acquiring the form they afterwards retain throughout the life of the animal. Some of the specimens soon threw off their covering and entered the third period of development.

Fig. 321.



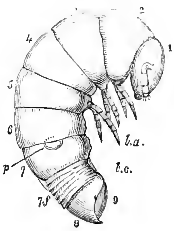
The animal was now greatly enlarged, and possessed three pairs of legs, but it still lay with these newly developed legs coiled up without voluntary motion. The amnion had been fissured at its anterior dorsal surface, and slipped off backwards from the posterior segments, and lay at the anal extremity, while the animal itself, with its limbs coiled up, appeared as if exhausted with these its first spontaneous efforts. No other signs of animal existence were given than occasional slight movements of the antennæ. The embryos thus passed from their apparently inanimate to an animated state of existence, from a condition in which they appeared merely to vegetate, endowed with no voluntary or instinctive powers, but like the vegetable formed entirely of an aggregation of cells, totally incapable of spontaneous motion, to one in which they became active beings, gradually acquiring voluntary and instinctive faculties both as regards the means of procuring nourishment and of preserving themselves from injury.

In *about an hour* after leaving the amnion the young Julus exhibited a marked change. Its head was elongated on the prothorax (2), the parts of the mouth were distinctly moveable, and the eye, a single ocellus on each side of the head, acquired a darker colour. The whole body had been increased at least one-fourth in bulk since leaving the amnion. It now measured about a line in length, and exhibited very distinctly the nine original segments. The seven anterior of these were strongly marked. In the *germinal space, (fig.* 321, *f*,) between the original seventh and eighth segments, *six new segments* were now developed. These were still very small, the length of the whole being equal only to that of one of the original segments. At the present time they did not form independent divisions of the body, but were covered by the common tegument, and thus appeared like supplementary parts of the seventh segment produced from the germinal membrane and interposed between the seventh and the penultimate segment (8), which, as before stated, is a permanent segment throughout the life of the animal. This latter fact shews that it is not merely by an elongation and division of the terminal segment that the body of the Julus is developed, but that it arrives at its perfect state by an actual production of entirely new segments; that these are new growths or formations which are in progress long before they are apparent to the eye, and that the original segments of the ovum into which the animal is first moulded are permanent segments throughout its whole life.

But still more curious is it that not only have new segments been formed as described, but that the common tegument by which they are now covered and which also invests the whole body as the true skin, has already begun to be detached preparatory to its being thrown off, as is shewn in the fact that the new segments are now seen beneath it; and it is further remarkable that this deciduation of the first skin of the animal had actually commenced before the bursting of the amnion. These circumstances explain the cause of the very quiescent state of the young Julus, and its almost and perhaps entire abstinence from food whilst this skin remains on its body. It is not until this skin is thrown off that the new segments become elongated, and the Julus then appears suddenly to have acquired six new divisions to its body.

The production of new legs is equally curious. Up to the present period the animal has but six legs (*fig.* 322, *b a*), but four additional pairs are nevertheless in the course of formation. These at present exist only as eight minute nipple-shaped prominences on the under surface of the sixth and seventh segments (*b c*), four on each, covered by the common tegument, which, we have seen, is becoming deciduous. The three single pairs of legs that now exist as the only locomotive organs are attached, one pair to the prothorax or second segment, one to the third and one to the fifth segment. The fourth, or segment intermediate between these last, never possesses any legs, but in the female contains the outlets of the organs of generation. The general appearance of the animal has now become less delicate, the head has acquired a darker colour, and a faint broad patch (*fig.* 322, *p*) is now making its appearance at the anterior part of the seventh segment. This patch, which is permanent through all the earlier changes of the animal, is of the greatest utility in determining the production of new segments. It is in the segment immediately posterior to this that the male organs find their outlet, a circumstance the more remarkable from the fact that this outlet is in the anterior part of the original germinal space, and at the bursting of the egg this is very near the termination of the body. Such was the condition of the young Julus one hour after leaving the amnion. It soon began to exhibit its animal powers, to shew the instincts peculiar to its species, and to be sensibly affected by external causes. In less than six hours from the bursting of the amnion the little creatures were in motion. At first the antennæ were the organs employed. They were moved slowly to and fro, and seemed to gain power by use. In a short time the limbs began to be extended, and the animal slowly raised itself upon them for the first time. Its first efforts at locomotion were exceedingly feeble, but it gradually gained strength. At the end of twelve hours the embryos crawled slowly about, but moving the antennæ briskly. On exposing them to a strong light a marked effect was produced in their movements. They evidently were greatly affected by it, and seemed instinctively to shun it. This was the first marked exhibition of instinct. Locomotion was at first performed very slowly but with instinctive care. The anal segment, previously to each step, was expanded like the anal leg of the larva of an insect, and being first attached like a true pro-

Fig. 322.



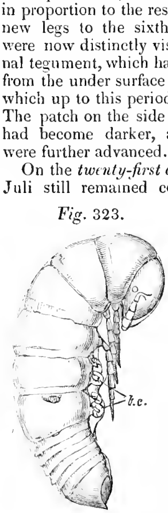
leg, and its step, as it were, measured, its body was carried forwards by an effort that extended, as in insects, from segment to segment.

At *twenty-four hours* after escaping from the amnion the young animals were lying together in a heap, but when disturbed seemed to have acquired more power of moving: they remained quiet except when aroused, and had not yet taken food. The only marked difference in their appearance, excepting that they had still further increased in size, was in the nipple-shaped protuberances on the sixth and seventh segments, the rudiments of future legs. These were now more distinct and mammiform. Ten hours later in the day they assumed still more the appearance of nipples projecting from the under surface of the segments. When examined in specimens that had been placed in spirits of wine, it became evident that these projections were occasioned by the developement under the deciduous tegument of four new, but exceedingly minute legs, complete in all their parts, each covered by its proper skin. The claws to the legs of the other segments were also more strongly marked. The new segments (*f*) were more developed, although still covered by the common tegument, and, as in the preceding state, forming only one division of the body, while a small space behind them indicated the point from which other new segments were to be produced.

On the *nineteenth day*, Mr. Newport found that the animals had acquired a little darker colour, but were still remaining quiet in their cells, and did not appear to have taken food. The enlargement of the body had not extended to the *prothorax*, which did not increase in size in proportion to the rest. The double pairs of new legs to the sixth and seventh segments were now distinctly visible through the external tegument, which had begun to be separated from the under surface of the old segments, to which up to this period it had closely adhered. The patch on the side of the seventh segment had become darker, and the new segments were further advanced.

On the *twenty-first day* (*fig.* 323) the young Juli still remained coiled up and perfectly quiescent, with their legs disposed side by side along the under surface of the body, like the pupæ of Lepidopterous Insects. The new legs had considerably increased in size, as well as the whole animal, although it had not taken food. The animal was still partially coiled up, but the skin that covered its body was greatly distended, more especially along the ventral surface. It was less able to move than before, the period of throwing off this skin being fast approaching: the double legs of the sixth and seventh

Fig. 323.



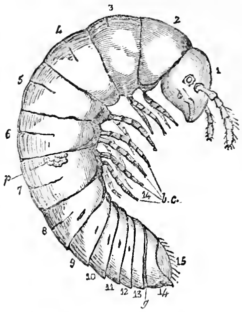
segments, inclosed in their proper skin, were now more elongated and very much enlarged, and the new segments were further developed as well as the germinal membrane. The external tegument was more extensively separated from the whole body, especially at the posterior part, and the head was retracted within it and bent on the under part of the thorax. It was thus evident that this tegument was not of recent formation, that it simply enclosed the animal as the whole had been previously enclosed in the amnion, as is proved by the circumstance that it extended smoothly over the whole body, antennæ and legs, and did not follow the inflection or reduplication of the proper surface of the animal like the true skin beneath it, but passed directly over the segments, and was simply protruded or distended by the growth of parts beneath, as in the instance of the new legs (*b*). Up to this period, therefore, observes Mr. Newport, the young Julus must still be regarded as in the embryo condition, although for a day or two after bursting the amnion, it possessed the power of locomotion and evinced some developement of instinct. At its next change of skin, when it enters what Mr. Newport regards as the fourth period of its developement, and when it has acquired fourteen pairs of legs, it assumes for the first time a condition analogous to the larva state of true insects on bursting from the ovum; the difference between the two being that the analogue of this tegument of the embryo in insects is slipped off at the bursting of the amnion on leaving the shell, while that of the Myriapod is not thrown off until some days after it has entirely left the ovum. This embryo condition of the animal will therefore explain the circumstance of its first acquiring a slight power of locomotion, and then remaining perfectly quiescent without taking food to prepare for this change—the third period of its embryo life.

The lower portion of the alimentary canal is at this time distinctly visible through the new segments, exhibiting a corrugated or folded appearance, an arrangement doubtless intended to allow of its sudden extension at the period of throwing off the skin and elongation of the segments. The colon is of a very dark colour and exhibits its thickened peculiar structure with its longitudinal muscular bands. Around its posterior part, Mr. Newport observed an aggregation of what appeared to be globular cells. They seemed to be part of the organs of generation in the course of developement. At first they were regarded as hepatic vessels, but this Mr. Newport considers could hardly be the case from the fact that each of these organs directly enters the canal as a straight vessel, but they might be vessels folded up to be unfolded suddenly, as in the case of the alimentary canal.

By the *twenty-sixth day* the young Julus casts off the covering in which it had hitherto been infolded, and enters the *fourth period of developement*, having now seven pairs of legs and fifteen segments to its body (*fig.* 324).

In this condition the antennæ were found to have become elongated by at least one-third of their original length, and exhibited six distinct joints. The eye still consisted of a single ocellus, but this was now surrounded by a darker coloured portion of the tegument. The new

Fig. 324.



legs (*b c*) were equal in size and length to the original ones, but were evidently more feeble. The transverse markings on the seven anterior segments (2-7) were very distinct, and the large brown patch on the seventh segment was much darker in colour. The whole body of the animal was considerably elongated. This was produced chiefly by the extension of the new segments (7 *g*) formed by the germinal membrane at the posterior part of the seventh, and which, in the early part of the last period, seemed to form a single distinct segment covered by the common tegument. The most anterior of these segments (8), now the eighth of the whole body, had acquired an extent equal on its upper surface to the preceding segment, but was shorter on its ventral surface. Like the preceding original segments it was divided into two regions by a transverse depressed line. The next segment in succession to this, the ninth, had also become enlarged to about one-third of the size of the eighth, and was, like it, marked transversely. The next four segments were each more developed than in the preceding state, but not to so great an extent as the others. The two remaining segments (14 15), the penultimate and anal, had undergone no change. They had simply acquired a little extension at the apex of the segment, and were now covered with a few scattered hairs. It is thus proved that the body is elongated, not by the division of the newly formed segments into others, but always by the formation of new ones in the germinal membrane that extends from the posterior margin of the antipenultimate segment to the penultimate, which last segment, with the anal, undergoes no change. That segment is always furthest advanced in growth which is immediately posterior to the last segment that possesses legs, and then the next in succession, until we arrive at the terminal ones—the penultimate and the anal—that never possess legs.

By the forty-fifth day more new segments had evidently been developed by the germinal membrane, soon to be exposed by another change of skin that was about to take place. The Julus ceased to eat, became torpid, and lay coiled up in a spiral form. The tegument of the body began to assume a whitish crustaceous appearance, and the animals secreted themselves beneath any dry covering, but avoided parts too wet. The principal changes in their general appearance were in the eyes, each ocellus being much more distinct, and in the germinal space, which was developed to its greatest extent, and distinctly exhibited the six new segments.

The change of skin, according to Mr. Newport, is effected in the following manner. The young Julus, when about to cast its integument, bends its body in a semicircular form, with its head inflected against the under surface of the second segment. In this condition it remains for several hours with its legs widely separated and the dorsal surface of the segments extended. The head is then more forcibly bent on the sternum, and a longitudinal fissure takes place in the middle of the epicranium, and is immediately extended outwards on each side posteriorly to the antennæ in the course of other sutures, the analogues of which Mr. Newport has described as the triangular and epicranial sutures. Through the opening thus formed in its covering the head is then carefully withdrawn, and with it the antennæ and parts of the mouth, and afterwards the anterior segments and single pairs of legs. The first and apparently the most difficult part of the shedding of the skin is its detachment from the posterior segments of the body and from the interior of the colon. To effect this the animal, which has been previously lying coiled up in a circular form, first straightens its whole body; it then forcibly contracts and shortens itself, especially at the posterior part, and by this means becomes greatly enlarged in bulk at its middle portion, but smaller at its extremities. During these efforts, which are some of the most powerful it is able to make, the skin becomes loosened from its posterior parts, and while still contracting its segments, the anal extremity, and with it the entire lining of the colon, become completely detached, and from these it gently withdraws itself within the old skin in which the body is encased as from the finger of a glove. This is precisely what takes place in the shifting of the skin in insects. Having effected this part of its labour all the posterior segments are again shortened; the animal once more disposes itself in a circular form, and after repeated exertions succeeds in bursting the tegument of the head in the part just described. As in the case of true insects the young Julus entirely empties the alimentary canal by voiding its fœces and ceasing to eat for one or two days preparatory to undergoing each transformation. When examined immediately before the change there are no other symptoms of new legs than slight elevations of the skin, and this perhaps accounts for the length of time occupied in the change, the new legs requiring time for further developement before the old skin is thrown off.

Having cast its skin and thus attained the fifth period of developement, the young Julus (*fig.* 325) has three ocelli on each side

Fig. 325.

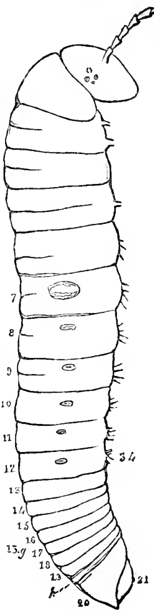


Fig. 326.

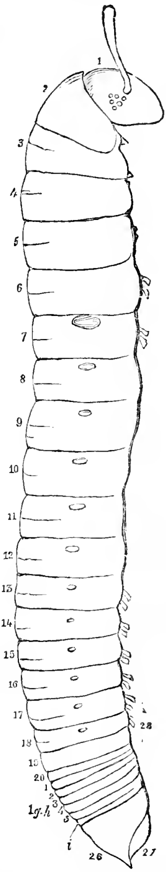

of the head, seven joints to the antennæ, thirty-four legs, and twenty-one segments to its body. On the forty-eighth day this has been accomplished, and the young Julus exhibits a marked alteration in its appearance. The antennæ are considerably longer than the head, with seven distinct joints, and, as in the adult, the apical one is short and inserted into the sixth. The single eye has disappeared, and in its stead three distinct ocelli, arranged in a triangle, have been developed. The new segments of the body produced at the former change of the animal, from the eighth to the twelfth inclusive, (8–12,) are now of the same size as the original ones, and each has developed from it two additional pairs of legs, so that the whole number of legs is now thirty-four. The thirteenth, or, if we may so name it, germinal segment of the last period, is less developed than the preceding ones, and is distinguished from them by the circumstances that it is smaller, possesses no legs, and has no lateral spot which exists on each of the preceding segments to the seventh, marking the existence of the *foramina repugnatoria*. The germinal space (13-19) which existed in the preceding period and was then seen to be forming segments, is now developed into six new apodal segments, from the 14th to the 19th inclusive, very much smaller and shorter than the rest, and a germinal space (*h*) is again forming between the last of these and the penultimate segment of the body, which, as above stated, undergoes no marked change. The whole body is thus composed of twenty-one segments, including the head. The first twelve of these are now perfectly developed, as well as the last two, the intermediate ones being only in their preparatory states. The animals at this period ate voraciously some decayed leaves, rotten elm-bark, and raw potato.

On the sixty-third day the Julus again changed its skin, and entered its sixth period of developement (*fig.* 326). It then had acquired twenty-seven segments to its body, which had greatly increased in size and was of a brown colour. It had now six distinct ocelli on each side of the head, and all the segments to the eighteenth inclusive were furnished with legs, of which it had now fifty-eight. Six additional new segments had also been developed to its body, as in the preceding changes anterior to the penultimate segment (1 *g h* 1 2 3 4 5 6), and the germinal membrane behind them (*i*) was still in further course of developement, the penultimate segment (26) remaining always unchanged. The six segments (28) from which legs had been developed had also the *foramina repugnatoria* marked with small spots, while the spots on the preceding six had become larger and darker in colour, and the animal might now be regarded as having acquired all the essential parts of its body, its subsequent growth doubtless being effected by a repetition of the same interesting phenomena.

The observations of Monsieur Gervais relative to the developement of the Scolopendroid Myriapoda, are the only ones on record with which we are acquainted; and although these are extremely desultory and incomplete when compared with the masterly researches of Mr. Newport concerning the Julidæ, detailed above, they seem to shew that the changes undergone by the Scolopendridæ, before they arrive at maturity, are scarcely less important than those we have been considering. M. Gervais studied more particularly the growth of *Lithobius*, (*fig.* 309,) Scolopendræ, which possess, when mature, fifteen pairs of feet, and also some individuals belonging to the genus *Geophilus*. A young *Lithobius* captured in the month of May was found as yet to possess only seven pairs of feet, ten segments in its body, two eyes on each side of its head, and but eight joints in its antennæ. Moreover, that only one segment, the anal, was deprived of feet, a circumstance which at once forms a remarkable difference between the young Lithobii and the young Juli, which latter have several apodal segments at the posterior extremity of the body. By the eighth of June the same Lithobius had fourteen joints in the antennæ, and eight pairs of legs, together with eleven segments to its body, including an apodal one for the anal segment.

Another *Lithobius* of nearly the same age had already three eyes on each side, and a third only ten pairs of feet, of which the two posterior were still rudimentary and scarcely formed. In another example, even when all the fifteen legs were present, the creature had not as yet got its full complement of eyes, there being only eight stemmata on each side, whilst in the adult animal the optic facets are numerous.

It appears manifest, therefore, that the Lithobii, like the Juli, have the number of their segments increased as well as of their legs, and of the joints of their antennæ; and, moreover, that the number of their eyes increases with their age, a remarkable fact, which M. Gervais seems to have been the first to signalize.

With respect to the manner in which the number of pairs of feet and of segments is increased as the young Lithobius grows older, M. Gervais gives us the following information: "Examined upon the ventral surface of the body, the pedigerous segments of an adult Lithobius are found to be nearly of size equal, but examined from above where they are, as it were, imbricated, some appear larger and others smaller. The largest of the pedigerous segments are the 1st, 3d, 5th, 7th, 8th, 10th, 12th, 13th, and 14th, the *three* last corresponding inferiorly to *four* half segments, and consequently to four pairs of feet. The 2d, 4th, 6th, 9th, and 11th, are smaller, and feet already exist upon these smallest segments even before the dorsal portion is developed, so that what is permanently observable in one of the posterior segments, which has superiorly only one shield, obtains also at this period for two of the posterior segments, which have as yet but one dorsal plate, the smaller of the two dorsal plates not having as yet made its appearance. This fact is remarkable, for if we suppose the same phenomenon to be constant with all the rings, it is easy to explain how at all ages there are fewer dorsal segments than there are pairs of feet."

As relates to the *Geophili*, M. Gervais assures us the process is, in them, altogether changed, another proof of the numerous differences met with in the physiology of the various genera of the class under consideration, but not having completed his researches upon this subject, the author of the memoir from which we have quoted has not as yet informed us of the result of his observations concerning the Geophilidæ.

Bibliography.—The literature of the anatomy and physiology of these animals is very limited. The reader may refer to the following works:—*Newport*, Philosophical Transactions for 1841. *Savi*, Observazione per servire alla storia di una specie di Julus communissima, Bologna, 1817. Bulletin des Sciences Naturelles, Dec. 1823. Rymer Jones*, General outline of the animal kingdom. Lond. 1841.

(*T. Rymer Jones.*)

NECK. Gr. τραχηλος; Lat. *collum, cervix;* Fr. *le cou;* Ital. *il collo;* Ger. *der Hals.* This word denotes that contracted, ribless portion of the trunk or column of support, which, in vertebrate animals, immediately sustains the head. Disease and accidental lesions so frequently submit it to surgical examinations and operative treatment, that familiar acquaintance with its intricate anatomy is of indispensable necessity to the practitioner.

The order which I shall adopt in the ensuing article is, first, to describe fully and in order the muscles and fasciæ of the neck, and subsequently the various regions into which it may be divided with the parts contained in them; the earlier portion giving, as it were, a mere skeleton view or diagram of the anatomy; the latter presenting the organs in their more natural, or regional arrangement, and treating of them in their living relations to disease, casualty, and surgical operation. I should recommend the student of this important part to pursue a similar plan; first, namely, thoroughly to impress on his mind those relatively firm and fixed textures which admit of practical use as landmarks, and not, till this task is completed and these anatomical boundary lines are vividly and individually before him, to fill up his sketch with important organs, or perplex his mind with their surgical relations.

I. The muscles.

The muscles of the posterior region of the neck and those of the shoulder having been described in a previous article (see Back), the remainder may be considered in three classes— 1. those which most nearly cleave to the vertebræ, are attached to their processes, and principally affect their motions; 2. those, chiefly in or near the median plane, which belong to the cervical portions of the respiratory and digestive apparatus, to the pharynx, larynx, tongue, and os hyoides; 3. the superficial muscles of the side of the neck, the sterno-cleido-mastoideus, and the platysma myoides. The *first class* includes—1. *anteriorly*, the longus colli and rectus capitis anticus major; 2. *laterally*, the scalenus anticus, scalenus posticus, and inter-transversales, with which may be reckoned the rectus capitis lateralis and rectus capitis anticus minor.

1. *Anterior vertebral muscles.—M. longus colli (Pre-dorso-atloidien:* Chauss.) is a thin elongated muscle, which occupies an extent in the pre-vertebral region, corresponding to the three upper dorsal and to all the cervical vertebræ. In form it is triangular, having its base at the bodies of these vertebræ, and its truncated apex at the middle transverse processes of the cervical region, and consists of three distinct, though united, parts, which would be represented by the three sides of such a triangle. One portion, the largest, is nearly vertical, next to the median line, and a direct flexor of the spine: it originates from the bodies of the three upper dorsal and four lower cervical vertebræ, as also from the intervening fibro-cartilages, and, ascending, is inserted by two slips into the anterior surface of the bodies of the second and third vertebræ. The second part is directed from the transverse processes of the third, fourth, and fifth cervical vertebræ, at which it arisesby tendinous slips,—upward and inward to be inserted into the anterior tubercle of the atlas, and it so continues to that bone the previous insertion of the muscle. The remaining part detaches itself from the main body of the muscle at the bottom of the neck, and ascends obliquely outward, to infix itself by small tendons at the anterior tubercles of the transverse processes of the third and fourth cervical vertebræ. The muscle may, in short, be described as passing from the bodies of the three upper dorsal and four lower to those of the three remaining cervical vertebræ, receiving above an oblique reinforcement from the middle transverse processes of the neck, to which it has likewise below detached slips of insertion.

M. rectus capitis anticus major (Grand-trachelo-basilaire: Dumas) lies closely on the vertebræ in the upper part of the neck, to the outside of the preceding muscle. It is an elongated, but thickish, muscle, arising by tendinous slips from the anterior tubercles of the transverse processes of the third, fourth, and fifth cervical vertebræ. These become fleshy, unite as they ascend, and are inserted into the under surface of the basilar process of the occipital bone, beside the median line, and just behind the spine, which attaches the raphe of the pharynx. Its inner edge overlaps the longus colli. These muscles correspond anteriorly to the great vessels of the neck, to the nerves which accompany them, and to the cervical portions of the respiratory and digestive tubes, but are separated by their own dense fascia from immediate relation to these parts. Their deep surface is in intimate connection with all the vertebræ and intervertebral discs, to which they correspond. Their action is inconsiderable; the rectus will slightly rotate and bend the head to its own side, or in conjunction with its fellow directly flex it. The longus colli, cooperating with its fellow, bends the cervical spine; or, acting singly, can slightly rotate by its higher fibres toward, by its lower fibres away from, the side on which the contraction occurs.

2. *Lateral vertebral muscles.—The inter-transversales colli* are almost described by their name. They form, on each side, a double series of small square muscles, occupying the spaces between the adjoining transverse processes, which afford them attachment by both borders of their surface. Arising from the lips, which the channelled upper surface of each transverse process presents, they ascend in each space to the borders of the process immediately above, and are there inserted. Between the inter-transversales antici and postici the spinal nerves of the region emerge, and the vertebral artery ascends.

Strictly analogous to these are the two small muscles which pass to the occiput from the transverse process of the atlas, the *rectus capitis lateralis* and *rectus capitis anticus minor.* The former would represent a posterior, the latter an anterior inter-transversalis. The former passes from the upper edge of the transverse process of the atlas to the transverse or jugular process of the occiput: the latter, on a plane anterior to this, from the anterior root of the transverse process and side of the anterior arch, inclines upward and a little inward, to be inserted into the basilar process of the occipital bone behind the rectus capitis anticus major, between its outer edge and the foramen magnum. The rectus capitis lateralis separates the vertebral artery from the jugular vein.

These muscles in approximating their points of attachment can give lateral flexion to the neck and to the head.

The *sculeni (Costo-trachelien:* Chauss.*)* are situated at the lower lateral part of the neck, extending from the transverse processes to the first two ribs, and are of triangular form. They have been variously described by different anatomists, some considering their fleshy mass as a single muscle, others distinguishing in it two, three, and even five parts. I shall adopt the more usual modern division, which recognises two muscles, *scalenus anticus* and *scalenus posticus.*

Scalenus anticus arises from the third, fourth, and fifth cervical vertebræ, at the anterior tubercles and notched extremities of their transverse processes, by slips of tendon, to which muscular fibres directly succeed, and descends with an inclination outward and forward to be inserted by a flat strong tendon into a roughness about the middle of the anterior third of the first rib. This insertion is important as affording a guide to the position of the subclavian artery, which, in arching over the rib, lies behind this tendon and separates it from the insertion of the scalenus posticus. It is triangular in shape and fleshy in nearly its whole extent: *externally* it presents a free border, from behind which emerge the elements of the brachial plexus and the subclavian artery; *internally* its origin adjoins that of the rectus capitis anticus major, from which it is demarked by the arteria cervicalis ascendens, and toward its insertion is separated from the longus colli by a space in which the vertebral artery ascends; its *anterior* surface is crossed from above by the phrenic nerve, and transversely by branches of the thyroid axis; its *deep* surface is separated from the scalenus posticus by the emerging trunks of the nerves, and the space between them, broadening towards the first rib, includes there the brachial plexus and subclavian artery—the latter being below and in front of the former, and in immediate contact with the rib.

Scalenus posticus, larger than the preceding, behind which it is situated, arises by six tendons, to which muscular fibres directly succeed, from the posterior tubercles of the transverse processes of the six last cervical vertebræ. The first slip (often partly derived from the atlas) is joined, as it descends, by the others in succession, and a large triangular muscle results, which has its base at the transverse processes and its apex at the second rib. It is inserted, first, by an anterior broad slip into the outer edge of the first rib, from the tubercle behind as far forward as the arterial impression in front; secondly, by a smaller slip, which is prolonged from the posterior surface of the muscle to the upper edge of the second rib near its tuberosity. This muscle corresponds *anteriorly* to the scalenus anticus, from which it is separated by the brachial plexus and subclavian artery; *posteriorly* to the levator anguli scapulæ; by its *inner* edge to its points of origin; by its *outer* edge to the serratus magnus and transversalis colli artery, to branches of the cervical and brachial plexus of nerves, and to the sterno-mastoid muscle; lastly, by its *inferior-internal* edge to the longus colli, from which it is divided by the anterior branch of the first dorsal nerve, and by the (generally) common trunk of the deep cervical and first intercostal arteries.

The action of the scaleni, as of the muscles previously described, consists rather in maintaining steadiness and resisting lateralisation of the neck, than in effecting any considerable movement. They may, however, in a slight degree, bend the neck laterally. The vertebræ being fixed, their muscles by acting together may elevate the first two ribs and so assist in inspiration. The scalenus anticus can, from its advanced insertion, act more effectually thus. This action is illustrated in all deeper inspirations; for these differ from ordinary breathing therein, that the chest is expanded by the elevation of the ribs and sternum, in its antero-posterior and transverse diameters, in addition to the ordinary increase of capacity which it gains by the descent of the diaphragm; and, in order to the effective action of the intercostals, the first rib must be rendered immoveable. The scaleni, in raising the anterior extremity of the first ribs, favour the advance of the sternum, and then rigidly fixing these bones enable the intercostal muscles to give to the ribs beneath that slight axial rotation by which the transverse diameter of the chest is increased.*

The intrinsic muscles of the larynx having already been described (see Larynx), and those of the pharynx being for future description (see Pharynx), our *second class* will comprise only the muscles of the os hyoides and tongue, viz. depressors of the os hoides, the *sterno-hyoid, omo-hyoid,* and *sterno-thyroid,* with its continuation the *thyro-hyoid;* its elevators, the *digastric, stylo-hyoid, mylo-hyoid, genio-hyoid;* muscles of the tongue, *hyo-glossus, genio-hyo-glossus,* and *lingualis*

The *sterno-hyoid* and *sterno-thyroid* are two riband-like muscles, having respectively the attachments denoted by their names,—situated beside the median line, so as to be divided

* Within the last year I have observed in two subjects an importantly anomalous insertion of the scalenus anticus. Its main bulk of tendon passed on both sides to an insertion *behind* the artery, a very small slip only taking the usual course. The strong flat tendon, which is usually so trustworthy a guide to the artery, would in these cases have involved an operator in the misfortune of surrounding the nerves with his ligature; and the circumstance illustrates the necessity of trying the effect of temporary pressure on a supposed arterial trunk, before conclusively tightening the ligature around it.

from their fellows on the opposite side only by the mesial raphe of the cervical fascia,—covering the trachea, thyroid body, with a portion of the larynx, and overlapping the sheath of the carotid vessels. They are isolated from each other, and from the other muscles of their neighbourhood, by processes of the cervical aponeurosis. The *sterno-hyoid* arises just within the thorax from the deep surface of the manubrium sterni, from the cartilage of the first rib, and from the ligament of the sterno-clavicular joint, and is separated from that of the opposite side by nearly the whole breadth of the sternum. As it ascends, it more nearly approaches its fellow, and the two are inserted side by side into the under surface of the body of the os hyoides, in close connexion, by their outer edges, with the omo-hyoid muscles, which are inserted beside them. The sterno-hyoid lies in its whole length on the sterno-thyroid muscle and its prolongation the thyro-hyoid, and these separate it from immediate contact with the important organs to which it is related.

The *sterno-thyroid* is broader and rises lower within the chest,—from the cartilage of the second rib, and from the adjoining surface of the sternum, on which it extends almost to the median line: its fibres ascend nearly vertically, and terminate at an oblique fibrous arch on the ala of the thyroid cartilage, and at the tubercles, to which this arch is attached; hence a muscle of similar volume is prolonged, (which may be described as rising from the oblique cord and from its points of attachment, but which, in direction, size, and form, accurately continues the sterno-thyroid,) and, after a course of an inch and a half, is inserted into the body and part of the cornu of the os hyoides, beneath the omo-hyoid and sterno-hyoid, and superficially to the thyro-hyoid membrane. To this is given the name of *thyro-hyoid*.

The sterno-thyroid and thyro-hyoid are covered throughout by the sterno-hyoid and in part by the sterno-mastoid and omo-hyoid muscles. The sterno-thyroid corresponds by its inner edge to the inferior thyroid vein,—by its outer edge receives the terminal branch of the descendens noni, by its deep surface covers the thyroid body and many of its vessels, the trachea and part of the larynx, and the sheath of the carotid vessels: by its origin it enters into the mediastinum, covers the great arterial trunks springing from the arch of the aorta and the brachio-cephalic veins. From these parts it is separated by the remains of the thymus gland. The thyro-hyoid muscle covers the superior laryngeal nerve and artery as they pierce the wall of the larynx. These muscles are fleshy in their whole extent, with exception of the short tendinous fibres, by which they have their origin and insertion: the sterno-thyroid has frequently a transverse tendinous intersection in some part of its course.

The *omo-hyoid* is a slender but long bi-ventral muscle, obliquely extending from the superior costa of the scapula to the os hyoides. It arises by short tendinous fibres at the root of the coracoid process, from the ligament which crosses the coracoid notch, and from the adjoining part of the costa, directs itself with a slight ascent towards the median line, and, in emerging from behind the clavicle, frequently derives a few fibres from its posterior edge. It contracts to a flattened tendon as it passes beneath the sterno-mastoid, and abruptly changes its direction from a nearly horizontal to a vertical course, by undergoing a trochlear reflexion in a loop of the cervical fascia,—and, again becoming fleshy, ascends beside and parallel to the outer edge of the sterno-hyoid, to which it is closely united,—to be inserted into the lower border of the hyoid bone at the junction of its body and cornu. The very important relations of this muscle will be more fully given in the detailed surgical anatomy of the region. It may for the present suffice to say, that, in crossing the direction of the sterno-mastoid muscle, it furnishes the subdividing line of the great triangles of the neck; that its posterior belly lies parallel to and just above the subclavian artery and brachial plexus, is covered by the platysma and partly by the trapezius, clavicle and subclavius, and crosses the scaleni and phrenic nerve: that its looped tendon is covered by the sterno-mastoid, and lies on the sheath of the carotid vessels, across which its anterior belly continues obliquely to run.

The two omo-hyoid muscles acting in concert are capable of depressing the os hyoides; but their chief action is of a different nature. Being contained in their whole bent course within a sheath of cervical fascia, they affect this membrane by their contraction, tensely spanning it across the median line in a space which extends from the hyoid bone to its clavicular attachment. This appears to be one of the consensual movements in the act of deglutition, designed to give, during that act, additional efficacy to the protection against atmospheric pressure, which Burns has shown to be an important function of the fascia of the neck.*

The *digastric* muscle is likewise, as its name imports, double-bellied; it passes from the mastoid process of the temporal bone to the symphysis of the jaw, but is looped down in its course to the side of the os hyoides. Its temporal attachment is to the groove, which is named from it, on the inner surface of the mastoid process: a large fleshy belly proceeds from this origin downward and forward, contracts to a round tendon, which usually pierces the stylo-hyoid muscle, traverses an aponeurotic ring lined by synovial membrane, which strongly binds it to the hyoid bone, near its lesser cornu, and is then reflected upward, expanding again to a strong muscular belly, which fixes itself by short aponeurotic fibres into the lower border of the jaw, at an oval depression beside the symphysis. Its tendon, just after passing through the fibrous pulley that maintains its curve, gives off a fascial process toward the median line: this attaches itself strongly along the upper edge of the hyoid bone, and

* Surg. Anat. of Head and Neck, p. 36. Glasgow, 1824.

internally joins a similar process from the opposite side to form with it a tendinous expansion, (often assisted by a few fleshy fibres from the anterior belly of the digastric,) which reaches from the os hyoides as far as the jaw, and contributes to support the floor of the mouth.

The relations of this muscle are complicated and important: the convexity of its curve is the upper limit of the anterior triangle of the neck; its concavity bounds a space, the area of which extends within the jaw to the myloid ridge, containing various parts, and named from the muscle the *digastric space;* its posterior belly crosses the external and internal carotid, the facial, lingual, and occipital branches of the former, the internal jugular vein, the three divisions of the eighth, the ninth, and the sympathetic nerve, the side of the pharynx, the trachelo-mastoid and styloid muscles, and the hyo-glossus. The sterno-mastoid and splenius cover its origin; the portio dura emerges at its anterior edge, along which the posterior aural artery runs, and round which the posterior part of the parotid gland is folded. Its anterior belly and tendon support the submaxillary gland, are covered by fascia and platysma, and correspond to the mylo-hyoid muscle, which is covered and strengthened by the aponeurotic expansion derived from the digastric.

The action of this muscle varies according to the fixity of the jaw: when the mouth is firmly closed, the contraction of the two bellies will draw the hyoid bone vertically upward, and communicate to the pharynx the movement of elevation, which adapts it for receiving the masticated food. A firm closure of the jaw, a contraction of the digastric muscles, and consequent shortening of the pharynx, (indicated by rising of the pomum Adami,) are well known acts in the process of deglutition. When the hyoid bone is fixed by its depressors (and perhaps in some degree retracted by the joint actions of the posterior belly of the digastric and of the omo-hyoid), the anterior belly, both passively as a reflected cord, and actively, in virtue of its muscular fibres, depresses the lower jaw and opens the mouth. Simultaneously, too, with its act of raising the pharynx, this muscle must tighten, by its posterior belly, the mesial aponeurotic expansion, which joins it to its fellow; and, by so doing, must assist the mylo-hyoid in raising the floor and reducing the capacity of the mouth. It fulfils, therefore, important uses in the mechanism of deglutition.

The *stylo-hyoid* muscle is an accessory to the posterior belly of the digastric, and arises from the outer surface of the styloid process, about midway from its base, by a small round tendon, which soon swells into an elongated body. This lies along the posterior belly of the digastric, parallel to its anterior edge, and, when it reaches the os hyoides, is inserted into the outer surface of that bone, at the union of its body and cornu, by short aponeurotic fibres. It usually divides, just previously to its insertion, to give passage to the tendon of the digastric. The portio dura of the seventh pair emerges between its origin and that of the digastric: in other respects its relations so entirely agree with those of the descending belly of that muscle, as do likewise its uses, that no particular description of these is necessary.

The *mylo-hyoid* muscles are so mutually dependent that they might almost be described as a single muscle. They arise on either side from the oblique or myloid ridge on the buccal surface of the lower jaw in its whole extent, i. e. from opposite the last molar tooth to the neighbourhood of the symphysis. The fleshy fibres, that succeed the short aponeurosis of origin, proceed parallelly toward the median line, and are inserted into a raphe, which reaches from the symphysis of the jaw to the body of the hyoid bone, and likewise into the upper border of the body of that bone. The anterior fibres are short; those which succeed progressively increase in length, and the posterior, which are fixed to the hyoid bone, are of all the longest. Each muscle is, therefore, triangular, having an outer edge by which it rises from the jaw, an inner edge of union with its fellow, and a posterior edge, which is seen to extend, in the digastric space, from the posterior extremity of the myloid ridge to the upper edge of the body of the hyoid bone, close to its cornu. The under surface of the muscle corresponds to the submaxillary gland and to the insertion of the digastric; its upper surface sustains the tongue and floor of the mouth,—from the mucous membrane of which it is separated by Wharton's duct, the sub-lingual gland, and gustatory nerve; it also corresponds to the hyo-glossus, genio-hyoideus, and genio-hyo-glossus, and to the termination of the lingual artery and nerve. The duct of the sub-maxillary gland winds round its posterior edge, in proceeding to open beside the frænum linguæ. The habitual state of this muscle is one in which it is rendered, with its fellow, convex downward by pressure of the superincumbent parts; and so its surfaces cannot strictly be said to face upward and downward, but with a modification of these directions respectively inward and outward. Thus the two muscles furnish a concave floor to the mouth, and it is only in their contraction, which accordingly diminishes the cavity, that this becomes strictly horizontal. Their action, especially when assisted by other muscles, is to propel the masticated food by lessening the capacity of the mouth.

The *hyo-glossus* is a thin quadrilateral plane of parallel muscular fibres, having the attachments which its name indicates. It rises from the entire length of the great cornu and adjoining part of the body of the os hyoides, on their upper surface, and ascends to be inserted into the side of the tongue. From beneath its anterior thicker edge the lingual artery emerges; its posterior thin border receives the insertion of the stylo-glossus; its deep surface corresponds to the genio-hyo-glossus and lingualis, from the former of which it is partly separated by the lingual artery; its external face is separated from the mylo-hyoid muscle by the lingual and gustatory nerves and duct of the submaxillary gland.

The *stylo-glossus* arises, as a round fleshy bundle, from the tip of the styloid process, and from the adjoining part of the stylo-maxillary ligament, becomes flattened into divergent parts, as it approaches the side of the tongue at the posterior border of the hyo-glossus, after a short course downward, forward, and inward, and is there inserted. A part is continued for some distance along the hyo-glossus, crossing the direction of its fibres, and interwoven with them; other fibres seem to bend into the substance of the tongue, near its base and at right angles to its axis. Its surface corresponds to the parotid gland, external carotid artery, internal pterygoid muscle, and mucous membrane of the mouth; deeply, it lies on the internal carotid artery, the superior constrictor of the pharynx, the tonsil and hyo-glossus.

The *genio-hyo-glossus* is a large, fan-shaped muscle, radiating from within the symphysis of the jaw to the entire length of the tongue, and constituting, with its fellow, the chief muscular bulk of that fleshy organ. It rises by a strong square mass of short tendinous fibres from the upper genial tubercle, and the fleshy fibres, which succeed, immediately and widely diverge; the highest bend upward and somewhat forward to the tip of the tongue; those, which next follow, occupy its entire remaining length, spreading with more or less obliquity into the substance of the organ, through which on a section they may be followed even to the dorsum: some of these may be traced beyond the posterior edge of the hyo-glossus, expanding on the side of the pharynx just above the hyoid attachment of the middle constrictor, and constituting the so-called lingual origin of the superior constrictor, (see PHARYNX); the remaining fibres complete the semicircular spread of the muscle, by passing downward and backward, to be inserted into the upper border of the body of the os hyoides. This muscle is opposed by its entire mesial surface to its fellow: their tubercles of origin are almost blended on the symphysis, and their fleshy fibres are only to be distinguished by a thin intermediate layer of adipose tissue: their upper edges raise the mucous membrane of the mouth on either side of the frænum; their lower edges extend to the hyoid bone in perfect parallelism to each other, and to the genio-hyoidei, which cover them; their outer surfaces, partly covered by the hyoglossi, form with these on each side the inner wall cf a triangular space (roofed by the mucous membrane and floored by the mylo-hyoid muscle) in which lie the terminal branches of the lingual and gustatory nerves, the lingual artery, the sublingual gland, and the excretory duct of the submaxillary.

Close at the implantation of this muscle in the tongue, between its fibres and those of the hyo-glossus, and crossing the direction of both, is a small bundle of fleshy fibres, which runs longitudinally from base to apex, and, since it has no fixed attachment, may most fitly be considered among the intrinsic muscles of the organ; it has been named *lingualis*. (See TONGUE.)

The *genio-hyoideus* is a strong cylindrical muscle intimately associated with the genio-hyo-glossus, and ordinarily co-operating with its posterior fibres. It rises by a square tendon from the inferior genial tubercle, beside its fellow of the opposite side and just below the genio-hyo-glossus. From this origin it directs itself backward and downward, and is inserted into the upper surface of the body of the os hyoides. Its insertion is somewhat broader than its origin: its inner surface corresponds to that of the opposite side; its upper surface is parallel to the genio-hyo-glossus, which it supports; its under surface rests on the mylo-hyoid, beside its raphe; its outer surface has similar relations to that of the genio-hyo-glossus, contributing with it to form the inner wall of the sub-lingual space just described.

The action of the extrinsic muscles of the tongue is modified and more nicely adapted to the delicate offices of speech by the co-operation of other and intrinsic muscles. These will be described in a future article (see TONGUE). Those already considered operate on the tongue *en masse;*—elevate, advance, depress or retract it, shift its volume to either side, and direct its extremity, by a kind of circumduction, over a wide range of surface. Thus, the stylo-glossus can elevate and retract, the hyo-glossus depress and lateralise; the anterior fibres of the genio-hyo-glossi, with the linguales, regulate the motions of the tip, while the genio-hyoid and adjunct fibres of the genio-hyo-glossi can cooperate in these movements by shifting the base of support in any direction. As the genio-hyo-glossus is of largest bulk, so is it of most various office in the tongue; by its posterior fibres it gives an elevation to the os hyoides by which the tongue is protruded from the mouth; or, half antagonizing this action by its middle fibres, it may so forcibly hollow the dorsum of the tongue as to direct its apex within the incisor teeth, and, with aid of the stylo-glossi, enable it to sweep the concavity of the palate; or, by this co-operating with either hyo-glossus and with the opposite lingualis and stylo-glossus, the tongue may be made, as it were, to probe with its eminently tactile extremity the entire length of the alveolar arches, or by a yet more definite contraction to exert suction on any spot with which its dorsum can have contact.

The *third class* includes the sterno-cleido-mastoideus and the platysma myoides.

The *sterno-cleido-mastoideus* is a long and powerful muscle, obliquely crossing the side of the neck, from the neighbourhood of the sterno-clavicular joint to the mastoid process of the temporal bone. It is fleshy in almost its whole extent; flattened at the extremities, but rather prismatic in the intermediate portion; and the anterior edge, which is more particularly continuous with the sternal origin of the muscle, and which, in certain positions of the neck, raises the integuments in a well-known diagonal relief, considerably exceeds the thickness of the posterior border. The name of the muscle is a summary of its attachments. It arises by two heads, which are usually separated by a distinct cellular interspace, corresponding to the sterno-clavicular articulation: 1. from the anterior surface of the first bone of the sternum close to its clavicular joint, by a very strong flat tendon which is directed upward and backward for the space of more than an inch, before terminating in fleshy fibres; 2. from the upper edge of the inner third of the clavicle by a thin origin composed of parallel aponeurotic fibres, which directly become fleshy, and take a nearly vertical course. As these two bundles ascend, the sternal, more oblique in its course, seems to overlap the other, and, both by difference of direction and by a line of cellular separation, can often be distinguished from it in the lower two-thirds of the neck; but in approaching the mastoid process they are indistinguishably fused together. The insertion is, 1. by a strong and rounded tendon into the mastoid process, of which it seems to embrace the tip and anterior border; 2. by a thin aponeurosis along the posterior edge of the process, and about a third of the superior semicircular line, which is continued into it.

This muscle, to which I shall have abundant occasion to refer in speaking of the surgical anatomy of the neck, has very important relations: the space between its heads corresponds to the bifurcation of the arteria innominata; and the broad band-like muscle, as it ascends, crosses in succession the subclavian and carotid arteries, the jugular and subclavian veins, the hypo-glossal, pneumogastric, phrenic, sympathetic, spinal accessory nerves, and a portion of the cervical plexus; the sterno-hyoid, sterno-thyroid, omo-hyoid, scaleni, levator anguli scapulæ, splenius, and digastric muscles, besides many lymphatic glands and branches from several of the nervous and vascular trunks which have been enumerated. Its *superficial* aspect corresponds to the integuments and platysma, to the external jugular vein and superficial branches of the cervical plexus; its thick *anterior* edge bounds the anterior triangle of the neck, receives branches from the external carotid artery or from its thyroid branch, and corresponds above to the parotid gland and posterior aural artery; its thin *posterior* edge limits the other great triangle of the neck, is pierced by the spinal accessory nerve, corresponds to a chain of lymphatic glands, and is wound round by the nerves and vein which lie on the surface of the muscle.

The two sterno-mastoid muscles acting together directly bend the head on the chest, and their joint action is well illustrated in an endeavour to raise the head from the supine position. But when the head is thrown far back, a predominance is given to the posterior fibres of the muscle, which being attached behind the line of the occipito-vertebral articulation, become then capable of increasing this direction of the head. The sterno-mastoid of one side, acting singly, rotates the head and flexes it with a lateral inclination to its own side, so as to bring the side of the head nearer to the shoulder, and to turn the face in the opposite direction.

The *platysma myoides (latissimus colli* of Albinus) is a broad, thin, membraniform muscle, which covers the side of the neck and lower part of the face, and is in its whole course subcutaneous. It arises by scattered fibres in the superficial fascia below the clavicle, and covers by its origin the upper part of the pectoralis major and deltoid, as also the space between those muscles, which corresponds to the coracoid process. This origin does not extend within an inch or two of the median line, but reaches as far outwardly as the acromial process. The fibres become more closely aggregated as they ascend, and the muscle accordingly narrows. Its direction is obliquely upward and to the median line; it passes over the base of the lower jaw, and its fibres again spread to their insertion: those which are posterior lose themselves in the skin covering the parotid gland and masseter muscle; others from this neighbourhood bend forward toward the angle of the mouth, and in some subjects constitute a very distinct horizontal *retractor anguli oris*, which is generally known as the *risorius Santorini:* some fibres from the middle of the muscle obtain a more fixed insertion about the base of the jaw and into the skin covering it; while the anterior portion of the muscle, which is most constant in its relations, is inserted into the lower lip by blending its fibres with those of the depressor labii inferioris, and by decussating toward the border of the lip and in the substance of the chin with the mesial fibres of its fellow.

This muscle is subcutaneous in its whole extent, and by its extremities intimately attached to the deep surface of the skin which covers it. In approximating its extreme attachments, it wrinkles the skin in a direction transverse to that of its fleshy fibres. It is a single and partial relique in the human subject of that general muscular investment, which fulfils various functions in different orders of Mammalia, as an appendage of the tegumentary system: rolling the hedge-hog in a ball, erecting the quills of the porcupine, and the bristles of the boar, or dislodging insects from the hide of grazing cattle. Its relations to the deeper parts in the neck will be detailed hereafter: between it and the cervical aponeurosis lie chiefly, cutaneous nerves and veins; branches from the cervical division of the portio dura are distributed to its upper portion, reaching the deep surface just below the angle of the jaw, and branches from the cervical plexus crossing the sterno-mastoid partly supply the platysma, partly pierce it in their course to the skin; the superficial pectoral branches lie beneath it till they reach the clavicle; the external jugular vein lies immediately beneath this muscle, and runs nearly parallel to its fibres, crossing transversely those of the sterno-mastoideus.

II.—Fasciæ of the neck.

1. The *superficial fascia*, or *subcutaneous areolar tissue*, presents characters in common with the same structure in other parts of the body, and is universally continuous with that

general investment; being prolonged without interruption, below, into the superficial fascia of the chest,—above, into that of the head and face. It consists here, as elsewhere, of two layers, which have the local peculiarity of being separated by the platysma myoides in the greater part of their extent. Its *deeper layer* occurs in the form of delicate, scarce, lax, fatless areolar tissue, interposed between the proper aponeurosis of the region and the platysma myoides, furnishing means for the loose gliding of this muscle, and continued, without adhesion or sensible change, into the adjoining regions. Its *subcutaneous layer* is of coarser materials and of less uniform thickness, is in close union with the skin, and follows its movements: it contains the variable amount of fat, which the region presents; and so, though it

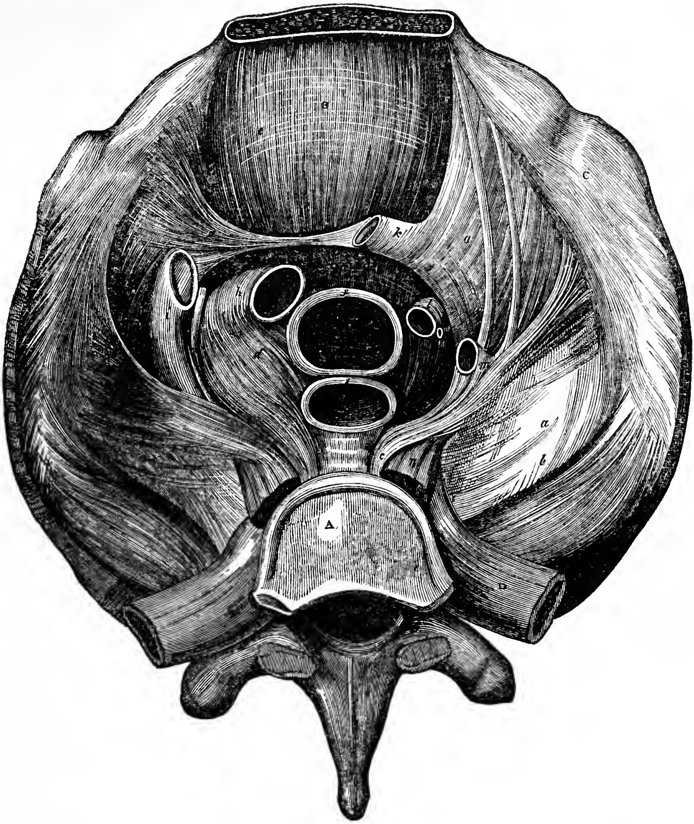
v, external jugular vein.
w, anterior jugular vein.
x, platysma and superficial fascia.

constitutes, in lean subjects, a manifest and resisting lamina, yet, in those of an opposite character, it is rendered indistinct by the predominant adipose tissue which occupies its areolæ. Along the side of the neck, from the clavicle to the jaw, these layers are kept asunder by the platysma myoides, which adds, as it were, a third lamina to the subcutaneous expansion; but both in front and behind, where the muscle ceases, they are in close relation, and constitute a single covering to those regions of the neck. The deep layer of this fascia is traversed by the cutaneous nerves and vessels, including the external jugular vein.

2. The *cervical fascia* is a proper aponeurotic investment of this region, and corresponds in its general characters to the fibrous sheathings of the limbs. Like these, it not only forms a general, compressive, and modelling cincture for the part, but, by various secondary splittings, furnishes dissepiments which isolate the different organs, and allot to each its proper sheath or fascial chamber. It may be briefly, but insufficiently, described as originating from a kind of *linea alba*, or mesial commissure in front, and in its backward course to the spinous processes furnishing a separate investment to every organ which it encounters, and attaching itself, both below and above, to the chief bony eminences which present themselves. (A section of it, as it thus *cellulates* the neck, is represented, with Bourgery's almost invariable accuracy, in a lithograph, (vol. vi. pl. 10,) from which the accompanying woodcut is copied.) It requires, in at least many regions of the neck, a more particular description than this summary contains; and I shall accordingly proceed to consider such portions of it with some detail. The *sterno-cleido-mastoideus* is ensheathed through its whole extent; the fascia, on reaching its anterior edge, is bi-laminated, encloses the muscle, and becomes again single at its posterior border. When this sheath is laid open by removing its anterior wall, and the muscle carefully everted from its prismatic cell, it will be seen that the posterior lamina is of greater strength than the removed anterior one; and this surface is the one from which the dissector may most conveniently trace the further spread of the membrane. He will find that the cervical fascia (of which the portion covering the sterno-cleido-mastoideus is but a secondary slip) extends itself from behind that muscle in all directions; inwardly to the mesial line,—outwardly to the trapezius,—upwardly to the jaw,—downwardly to the clavicle. *a.* Traced *inwardly*, its arrangement differs in the upper and lower parts of the neck: 1. in that below the os hyoides a superficial lamina covers the subhyoid muscles, joins its fellow in the median line, and is fixed below to the interclavicular notch of the sternum; a second, thin process divides the sterno-thyroid from the sterno-hyoid muscle; a third, stronger one, passing between the sterno-thyroid and air-tube, covers this latter organ and the thyroid body, is attached below to the inner surface of the manubrium sterni, internally joins the layer from the opposite side, and helps with it to form a raphe, reaching from the os hyoides to the sternal notch. Previously to the divisions here mentioned, the fascia encloses the flat tendon and anterior belly of the omo-hyoid muscle; and in a line, which will presently be more particularly indicated, covers the carotid artery, jugular vein, and nervus vagus. Just external to these parts, along the outer edge of the jugular vein, it detaches a delicate process, which passes behind the vessels, separating them from the sympathetic nerve, and is continued inwardly to join its fellow from the opposite side, as a cellular clothing to the œsophagus. 2. Above the os hyoides, the arrangement of the fascia is simpler; covering the mylo-hyoid and submaxillary gland, and inclosing the anterior belly of the digastric, it is fixed to the lower border of the symphysis, and hence to a mesial raphe as far as the os hyoides. It has some deep connexions, to which I shall return directly; and, to the sheath of the great cervical vessels it preserves the same relations as below, its deepest process losing itself on the pharynx. *b.* Traced *upwardly*, the fascia is seen to split on the inferior edge of the digastric muscle; the superficial lamina is attached, behind, to the mastoid process,—in front, joining the part last described, to the lower edge of the jaw,—and, intermediately, ascends upon the parotid gland, which it invests; the deeper layer is fixed to the styloid process of the temporal bone, and gives origin to a remarkable septal slip, (sometimes called the stylo-maxillary ligament,) which, just in front of the posterior belly of the digastric, passes outwardly, is inserted into the deep surface of the superficial lamina and into the angle of the jaw, so serving to separate the space, circumscribed by the digastric muscle, into two parts, and isolating the parotid gland, which occupies the posterior of these, from the submaxillary, which is situated in the anterior one. Further, this deep layer (joined by a slip from the fascia, which covers the submaxillary gland and is attached to the jaw) prolongs itself around Wharton's duct, between the mylo-hyoid and hyoglossal muscles, and likewise furnishes origin to the investing cellular tissue of the pharynx. *c. Below*, the cervical fascia attaches itself around the insertions of the muscles, which it incloses, viz. towards the median line to the notch of the sternum, and—with the sub-hyoid muscles—to the deep surface of the manubrium and to the cartilage of the first rib, and then to the clavicle in its entire length, both around and between the sterno-cleido-mastoid and trapezius. In descending to the clavicle, it ensheathes the posterior belly of the omo-hyoid; and a firm process of it, folded around this muscle and directed backward to the levator anguli scapulæ, is infixed along the superior costa of that bone, and circumscribes the so-called omo-hyoid space. *d.* Traced *outwardly and backwardly* the fascia covers in the interval between the trapezius and sterno-mastoid (posterior triangle) from the clavicle to the occiput, and, on arriving at the anterior edge of the trapezius, splits to enclose it. The further distribution of it, in this direction, is in ac-

Fig. 328.



Shews from below the cervico-thoracic septum constituting the roof of the thorax, and giving passage to the great vessels. It represents a transverse and horizontal section through the second intervertebral disc, and parts at the same level.

A, second dorsal vertebra.
B, tranverse division of the manubrium sterni.
C, first ribs.
D, vertebral extremity of second ribs.
a, ***a***, fascia, extending between the great vessels and first two ribs.
b, ***b***, its insertion at the first ribs.
c, ***c***, its insertion at the second vertebræ.
d, ***d***, lamina between the great vessels, attached centrally to them,—in front to the sternum, where it forms a cul-de-sac,—and behind to the second dorsal vertebra.
e, the aponeurosis, extending within the sternum.
f, the trachea.
g, the œsophagus.
h, the arteria innominata.
i, the right vena innominata.
k, the left vena innominata; tranverse band uniting the two sides of the aponeurosis.
l, the left carotid artery.
m, the left subclavian artery.
n, section of the musc. long. colli.

cordance with the general law of its arrangement for the separation of muscles; is destitute of any particular surgical interest, and forms no exception to the general observations given in a preceding article. (See Back.)

A portion (but a very distinct portion) of this great aponeurosis is the *pre-vertebral* fascia. It extends from the occiput—to which it is fixed in front of the *recti capitis antici*—to the inlet of the chest, where it adheres, beside the longus colli, to the neck of the first rib; it binds down the pre-vertebral muscles, is attached deeply to the tips of the transverse processes, and receives by its surface a septal slip from the cervical fascia just externally to the sheath of the vessels. An important process is the prolongation which it sends downward on the scaleni; and which partly fixes itself to the rib around the attachments of those muscles, partly extends itself, as a strong infundibulum on the brachial plexus and subclavian vessels. From this—their fascial sheath—an horizontal slip detaches itself and passes forward to the posterior surface of the clavicle, where it fixes itself by two laminæ; the upper of these is inserted just above the attachment of the subclavius muscle, while the lower is continued into the sheath which that muscle derives from the coraco-costal fascia. The horizontal process separates the cavity of the axilla from the lower triangle of the neck, and the vaginal prolongation, contracting as it descends, becomes lost in the sheath of the axillary vessels.

Finally, as these various layers of fascia attach themselves about the inlet of the thorax, (the sub-hyoid part of the cervical aponeurosis in front, and the pre-vertebral behind,) they are connected to one another and to the large vascular and mucous canals, which traverse that passage, by certain horizontal processes of fibrous membrane, which constitute together a kind of diaphragm, or *cervico-thoracic septum*. Viewed from below this would seem a vaulted membrane, overarching the tops of the pleuræ, and giving infundibular passage to the great arterial and venous trunks and to the trachea; viewed from above it would present the various deep implantations of the cervical fascia, and a surface without aperture or breach of continuity, prolonging itself in several directions round the canals, which it thus indirectly transmits. The obvious use of these arrangements is to supply adequate resistance to the atmospheric pressure, which, were it not borne off by the tension of these fasciæ, would at each inspiratory effort tend to flatten the trachea, or to rush through the upper strait of the thorax. Allan Burns, who in this country first drew attention to the importance of the cervical fascia, carefully illustrates its functions in health, and the inconveniences which accompany its destruction. (Op. cit.)

III.—Regional distribution and surgical anatomy of the neck.

The posterior parts of the neck having been described in a previous article (see Back), the present will be restricted to an account of its anterior aspect.

The cervical vertebræ (by their bodies, intervening fibro-cartilaginous discs, and transverse processes), together with the anterior and lateral vertebral muscles, already described, compose the skeleton and supporting fabric of this region; the anterior fibres of the trapezii, as they descend on either side to the inner edge of the acromio-clavicular arch, form its lateral boundaries; the larynx and trachea (covered by their own extrinsic riband-like muscles, and partly covering the pharynx and œsophagus) separate the nearly symmetrical halves of the neck by constituting along its median line a marked columnar relief, in the recesses beside which lie the great cervical vessels; the base of the skull and the oblique line of the jaw are the upper limits of the region; the clavicle (just behind which the great vascular and nervous trunks of the upper extremity course) bounds it below; the skin, the platysma myoides (in its cellular covering), and the cervical aponeurosis are stretched across it as general investments; while the last-named fascia ensheathes the various parts by special processes from its deeper surface.

Thus, in general terms, the structure of the neck may be described; but, for the more precise and particular account, which the importance of its anatomy renders necessary, a division of it into spaces of small extent is convenient. The arrangement, which I propose following, differs but little from that usually adopted, and, perhaps, somewhat exceeds it in precision.

The upper limits of the neck having been stated as the oblique line of the jaw and the base of the skull (which parts, as we shall presently see, are brought into relation by the attachments of the constrictor pharyngis superior), our highest region has in that direction these parts for its boundary, and extends below as far as the curve of the muscle, from which it is named the *digastric* space.

A small space that can hardly be referred to the digastric,—from which it is separated by the vaginal process of the temporal bone, and by attachments of fascia,—and which, from the importance of its contents, deserves careful consideration, is the *posterior pharyngeal;* it lies closely beneath the base of the skull, (from the vaginal process to the median line) between the pharynx and spine, and includes the carotid, jugular, and condylic canals, and the organs traversing them.

If now an oblique line be carried across the neck, from the sterno-clavicular articulation to the tip of the mastoid process, it divides, as a diagonal, the remaining quadrilateral surface of the neck into two triangles; an anterior one having its apex at the sterno-clavicular joint, and its base along the posterior belly of the digastric muscle; a posterior one, having, its base at the inner two-thirds of the clavicle,—its apex at the mastoid process,—its posterior side formed by the trapezius,—its anterior border defined by the imaginary line which demarks it from the anterior triangle. The omo-hyoid muscle, in its reflected course, crosses both these triangles, subdividing them; and since the angle of its bend falls just on the line of their separation, and since it proceeds from behind the outer third of the clavicle to the body of the hyoid bone, it acts as a second diagonal in the neck, dividing each into an upper and a lower triangular space. These four triangles will be described in detail; and since the sterno-mastoid (which is too substantial to be treated as a mere boundary-line) enters into all of them, and has to parts of each relations of the extremest practical importance, some separate, chiefly recapitulatory, consideration will be given to its relative anatomy. Finally, to ensure for the organs of the median line the consideration they require (the usefulness of which mainly depends on their being viewed connectedly), it may be well to take them in that relation.

Thus, (1) *a region of the median line*, (2) *an antero-inferior*, (3) *an antero-superior*, (4) *a postero-superior*, and (5) *a postero-inferior triangle*, (6) *a digastric*, and (7) *a posterior pharyngeal space*, are to be severally considered; and a few preliminary remarks may be given to the tegumentary parts, which are more or less common to all.

The *skin* is fine, thin, and extensible, especially below and in front; becoming coarser and more adherent toward the upper part of the posterior triangle; it frequently presents some transverse wrinkling above the hyoid bone, which seems to depend on the platysma myoides; here, too, the follicles are larger and more abundant than in the other parts of the neck, and, in the male subject, the surface is overgrown by the beard. The *subcutaneous cellular tissue* has already been described; in the upper part of the posterior triangle it becomes almost inseparably confounded with the cervical aponeurosis; the *platysma myoides* lies between its layers and keeps them apart over the greater surface of the neck; the fibres of this muscle are absent in the lower part of the anterior, and upper part of the posterior triangle, and at these spots the two layers of the superficial fascia fall together and are nearly confounded. In the deeper lamina of this texture, subjacent to the platysma in the parts where it lies, run the *superficial veins and nerves*. The *external jugular vein* commences in the parotid gland, usually by radicles, which correspond to the terminal branches of the external carotid artery, temporal, internal maxillary, and transverse facial; pierces the fascia near the angle of the jaw, and directs itself almost vertically toward the middle of the clavicle, in the deep layer of superficial fascia: just at the edge of the clavicular insertion of the sterno-mastoid muscle it bends inward, pierces the aponeurosis, and discharges itself into the subclavian vein. It thus very obliquely crosses the sterno-cleido-mastoideus from its anterior to its posterior edge, separated from that muscle by its fascial sheath; the auricular nerve runs upward parallel to its posterior border; the platysma covers it in its whole course with fibres which cross its direction; its place of discharge into the subclavian vein is usually just opposite the scalenus anticus, covered by fascia and by the sterno-mastoid muscle. It receives superficial occipital, superior and posterior scapular veins; branches from the posterior triangle of the neck, and from the trapezius; it has uncertain and irregular communication with the anterior jugular vein, and receives a certain, though not regular, branch from the internal jugular; this is usually given to it at the lower part of the parotid, or on its emergence from that gland, and occasionally seems to constitute its commencement. Obvious surgical inferences from the anatomy of this vein are: the relief that its communication with the internal jugular enables it to give, when opened in cases of cerebral congestion; the eligibility of its line of passage over the thick belly of the sterno-mastoid for that mode of venesection; the necessity for dividing some fibres of the platysma transversely to their length (by an incision nearly in the direction of the sterno-mastoid) in order to obtain a clear opening and free jet of blood; the need for care in this operation, but still more in proportion as the vein is wounded lower in the neck, to hinder the possibility of air being inspired through its cavity.

The *anterior jugular* vein is an irregular subcutaneous supplement to the external: it commences in the submental region, near the hyoid bone; descends vertically beside the median line, receiving branches from the larynx, and sometimes from the thyroid body; on arriving at the sternum, or near that bone, it bends horizontally outward, piercing the fascia, and runs behind the origin of the sterno-mastoid, to throw itself into the subclavian vein, somewhat within the termination of the external jugular. It generally has free communications with its fellow and with the internal and external jugular. Its size is in inverse proportion to that of the external; and, in absence of this, it is generally a very considerable branch; it is sometimes single and mesial; but more usually two exist, which are commonly of unequal calibre.

The *superficial nerves* are of two classes, being partly derived from the cervical plexus, partly from the portio dura.

The cervical plexus sends its superficial branchings in three directions: the *mastoid* and *auricular* pass upward; the *anterior cervical* runs forward; the *supra-clavicular* and *super-acromial*, as their names denote, descend more or less obliquely.

The *mastoid*, originating from the second cervical nerve, winds upwardly across the splenius, and almost parallel with the posterior edge of the sterno-mastoid, which it crosses in its ascent. It pierces the fascia soon after its origin, and becomes subcutaneous. Its distribution is entirely to the skin of the mastoid and occipital regions. The *auricular*, rising from the second and third cervical nerves by a trunk, common to it with the anterior cervical, directly pierces the fascia, loops round the posterior edge of the sterno-mastoid, and ascends across its surface (the fascial sheath intervening) toward the angle of the jaw; where, after supplying twigs to the integuments over the parotid gland, it divides into terminal branches, which are distributed to the external and internal surfaces of the auricle and to the adjoining integument, in a manner which need not be particularised in the present article. In crossing the sterno-mastoid it is parallel to the external jugular vein, and behind it. The *anterior cervical* rises in common with the last, and pierces the fascia in its company; bends at right angles across the sterno-mastoid muscle, and is itself crossed by the external jugular vein. On arriving at the edge of the muscle, it divides into many twigs, which, traversing the platysma at several spots, distribute themselves to the skin of the anterior triangle of the neck, and to that of the adjacent part of the digastric space. This nerve, where crossed by the external jugular vein, gives one or two minute twigs, which follow its direction toward the angle of the jaw.

The *supra-clavicular* and *super-acromial* are the two superficial branches in which the plexus terminates: as they descend, they divide into a lash of twigs, which diverge in the posterior triangle of the neck, and at various heights pierce its fascia, become subjacent to the platysma, and contribute to supply it. Their ultimate branching takes a very wide range: the inner filaments obliquely cross the clavicular origin of the sterno-mastoid; the outer, the anterior fibres of the trapezius; the middle ones, the clavicle itself; and are distributed, in their respective regions, to the integuments of the scapula, shoulder, chest, and sternum.

The branch from the *portio dura*, which enters the neck, is the lower division of its cervico-facial part. From near the angle of the jaw, where it traverses the fascia, it passes toward the hyoid bone, and supplies the platysma from its deeper side. Some of these twigs, approaching the cutaneous surface of the muscle in the anterior triangle of the neck, communicate with filaments of the anterior cervical nerve.

1. *Mesial region of the neck.*—This presents different relations, as considered above or below the level of the *os hyoides*.

Above the os hyoides, and extending from the body of that bone to the symphysis of the lower jaw, is the narrow space which separates the anterior bellies of the digastric muscles. It is an elongated triangle, broadest below—where the tendons of the digastrics are kept apart by the body of the hyoid bone—having its apex above, where these, having expanded into the fleshy anterior bellies, are infixed side by side at the median line of the jaw. The platysmata in their cellular sheath cover this space, and sometimes decussate across it with each other. The cervical aponeurosis likewise extends over it, adhering to its bony limits, and strengthened by the tendinous slip, which is derived from the digastric. Deeper than the digastrics are seen the fibres of the mylo-hyoid muscles, meeting in the median raphe, which runs along the space. The natural direction of this raphe is almost antero-posterior, and that of the fibres which meet in it almost horizontally transverse: but when (as in any operation on this part of the neck) the head is thrown back and the chin elevated, the raphe presents a considerable downward slope, and the fibres of the mylo-hyoid have a corresponding obliquity. The same observation applies to the deeper fibres which course from the tubercles within the symphysis to the body of the hyoid bone—those, namely, of the genio-hyoid and genio-hyo-glossal muscles. This little region can hardly be said to have any special surgical relations; it contains neither vessels nor nerves of size; its injuries only assume importance when they extend beyond it into the adjoining digastric space; its diseases derive no peculiarities from their situation, and for the most part belong to the integuments, which are vascular, highly folliculated, and in the male densely bearded: sycosis often extends to them, and they are a frequent seat of sebaceous tumours.

Below the os hyoides, the anatomy, which involves the surgical relations of the larynx and trachea, becomes of extreme importance. Between the two layers of the fascia superficialis the platysma no longer intervenes; they accordingly lie together and are blended. The vaginal processes of cervical fascia, which have isolated the sub-hyoid muscles, become united into a strong and single raphe along the middle line, from above to within a short distance of the sternal notch; but here the layers remain distinct, a superficial one fixing itself to the notch and to the interclavicular ligament, while the deeper one descends with the muscles into the mediastinum. The interval contains loose cellular tissue, and sometimes (as Burns noticed) an absorbent gland. Accordingly, in the very median line, an operator may expose the larynx, trachea, or thyroid body without dividing or displacing any portion of muscle; but a lateral deviation from this imaginary line would imply an exposure of the sub-hyoid muscles on one side or on the other. Indeed, the muscles so nearly approach to the line in question, and constitute in their laminar arrangement so useful a guide to the subjacent parts, that the bare possibility of avoiding them is wisely neglected, and the surgeon learns from them his nearness to the organs which they cover.

In tracing, from the hyoid bone downward, the irregular profile of the air-tube, the finger may distinguish through the integument the following changes of outline. 1. A horizontal semicircular notch, limited below by the prominent angle of the thyroid cartilage, and corresponding, in the interval of the muscles, to the thyro-hyoid membrane; the lateral parts of this give passage, as we shall presently see, to the laryngeal artery and nerve, but its mesial part, with which alone we are now occupied, has only a small twig from the thyroid artery ramifying over it: the membrane is thick, and composed of strong vertical fibres in the median line; it becomes weaker and of laxer tissue in proceeding backward. Its deep aspect contributes to the skeleton of the pharynx, and corresponds to the epiglottis, from the attached portion of which it is separated only by cellular tissue and the epiglottidean gland; while, above, the mucous membrane, in being folded forward to the epiglottis, intervenes between it and the membrane. This notch is frequently invaded by the knife of the suicide; and there is perhaps no part of the neck on which a gash may be inflicted with less serious injury: the large vessels are far removed, and the larynx lies below the blade, which may, if near to the hyoid bone, enter the pharynx above the epiglottidean fold of mucous membrane, leaving the epiglottis unhurt, or, if more nearly approached to the thyroid border of the space, may partly or entirely sever that cartilage from its inferior attachments. No special surgical operation belongs to the space; if indeed we except a proposal made by M. Malgaigne* for reaching the larynx through it, which has not yet received the sanction of practice. 2. The angle, in which the alæ of the thyroid cartilage meet, having—under the quaint name of *pomum Adami*—its extreme prominence above. Within it are the essential organs of voice, which, buckler-like, it protects: the inward aspect of its angle attaches the vocal ligaments; its outward jutting marks their length, and measures the development of the larynx. Hence the *pomum Adami*, as indicating by its prominence that matured growth of the organs of voice, which belongs to male puberty, is a physiognomical character of sex. Desault's mode of laryngotomy consists in a vertical division of this angle from below upward, and has the recommendations of easy performance and of efficiency for the extraction of a foreign body. That it invades parts of high functional endowment and extreme irritability,—that ossification of the cartilage may unexpectedly prevent its completion,—that perfect reunion of the divided structure is uncertain—are alleged as objections to it, and perhaps over-estimated as such; for to the first may be answered, that the operation is of *relief*, and hence little likely to aggravate an irritation, the cause of which it removes; to the second may be conceded, that the mode of operation is not eligible for cases likely to present the bony deposit referred to; and against the third may be adduced the evidence of the French surgeons, by whom chiefly the operation has been performed, that the parts are as quickly repaired, and their functions as completely recovered, as after any other mode of operative procedure. As regards its anatomy, nothing can be easier than to lay bare the pomum Adami; a division of the skin, of the superficial and proper fasciæ, with some lateral displacement of the sub-hyoid muscles, will suffice for its exposure: and, for its division,—the closest following of the medial line, in order that the knife may pass *between* the vocal ligaments, leaving both uninjured, is the chief precaution to be observed. The upper edge of the glottis is on a level just below that of the superior thyroid notch. The prominence of the thyroid cartilage and the unyielding support which the borders of its arched surface receive from the bony column behind it, render it liable to be crushed by any considerable, direct, antero-posterior violence. Such has, more than once, been the cause of immediate death where a straightforward blow has reached the larynx in prize-fighting; and such, too, is a not infrequent effect in death by hanging, especially where, as in the English mode of judicial execution, the rope is made to tighten itself jerkingly. The thyroid cartilage is sometimes partially divided in attempts at self-destruction, which it commonly frustrates by defending more important parts. 3. A depression which answers to the crico-thyroid ligament: it is here that the usual operation for urgent glottic dyspnœa is performed. The common integuments and the fascial raphe cover the little interspace in question, which is safely reached—between the crico-thyroidei—by displacing in a slight extent the sub-hyoid muscles. It has about half an inch of transverse breadth, and about a third of an inch of height,—is bounded by the inferior thyroid notch and by the anterior part of the circumference of the cricoid cartilage; which borders give attachment to the strong yellow elastic membrane that closes the space. This depression is so readily felt through the integuments—its boundaries are so definite and its relations so simple, as to render it a peculiarly eligible spot for bronchotomy, when suddenly and urgently required. A small artery sometimes forms, with its fellow of the opposite side, a transverse communication across this membrane, and its presence has been much insisted on as a circumstance of practical importance: it is of extreme minuteness, and by no means constantly present: it is the *crico-thyroid*, and arises from the thyroid branch of the external carotid, near the upper angle of the thyroid body, and runs across the membrane toward the median line. The necessity for haste is commonly of too urgent a character to admit of any deliberate, layer-by-layer, dissective operation: a single steady puncture with a canulated trocar, or with a bistoury—directly followed by a tube—is the usual mode of conducting it. In such instances the minute artery can hardly be avoided with certainty, but neither can its division be injurious, since the closely fitting canula will secure the cavity of the air-tube against its trifling hemorrhage. In the rarer cases, where time is allowed for a slower division of the tissues, it would be desirable not to puncture the membrane till the artery, if present, had been disposed of. It usually lies near to the border of the cricoid cartilage, and might easily be drawn downward away from injury; or its division might be rendered harmless by torsion, or by a fine ligature. In the more extemporaneous mode of laryngotomy the bistoury should be guided flatly, close beneath the thyroid cartilage; in so making a transverse division of the membrane, it is parallel to the line of the artery, but above its usual position. 4. The slight prominence of the cricoid cartilage, and the series of tracheal rings—becoming progressively deeper toward the sternum,—are next felt. In some subjects their chain is seemingly interrupted by a transverse fleshy eminence (which, however, is in health generally imperceptible through the skin), the isthmus of the thyroid gland. To the lateral portions of this body I shall presently return: the isthmus is its only part having relations in the median line, which it crosses to a very variable extent. Most frequently it measures about half an inch in breadth, and corresponds by its middle to the second ring of the trachea: but from this, its normal extent may vary on the one hand to the extreme of entire absence—on the other to that of being an uncontracted, flattened union of the lateral lobes, which it may so equal in its vertical dimension. Downward from its lower edge, in front of the remaining rings of the

* Médecine Opératoire, 1840, p. 517.

trachea, passes the inferior thyroid venous plexus, on a level with which would be found, in rare cases, the middle thyroid artery (of Neubauer) ascending from the aortic arch: these vessels are covered by a layer of fascia dividing them from the sterno-thyroid muscles. These parts are variously involved in the two remaining modes of bronchotomy; one of which—the tracheal—consists in dividing three or four rings of the tube, below the isthmus of the thyroid gland; the other—the crico-tracheal—in dividing its upper rings and with them the cricoid cartilage of the larynx. The first—*tracheotomy*—(after a vertical division of the tegumentary parts and a separation of the muscles from the lower part of the larynx to the sternum) exposes the tube in that portion of its extent in which it is deepest and most nearly related to vessels. The operator is required to bear in mind the possible presence of a middle-inferior thyroid artery, lest he wound it inadvertently; he must avoid, or, before opening the air-tube, must secure the inferior thyroid veins; in recollecting the great lateral mobility of the trachea and its close parallelism to the carotid arteries in the lower part of the neck, he must guard against any oblique glancing of his knife, by which these great vessels might be injured; in proceeding to divide the cartilaginous rings, he must commence below and on a completely exposed part of the tube, and with the blunt border of his knife toward the middle line of the sternum, and with its point directed slightly upward, lest (as might happen in neglect of these precautions) the great vena innominata, transversely crossing the tube just below the level of the sternum, or the large arterial trunks, which are there diverging from the median line, should sustain injury: nor must he rudely transfix the tube and encounter the risk of puncturing parts, normally or abnormally behind it.* The second operation, *crico-tracheotomy*, first proposed by Boyer,† pretends to preference over that just mentioned, on the ground of obtaining an equally free opening with less invasion of important parts. Indeed, although M. Boyer, in proposing it, seems to have considered the section of the thyroid isthmus inevitable, and accordingly included its division in his estimate of risks,—perhaps even that objection might be withdrawn from the operation, if performed in exact agreement with his description; since the finger may depress the thyroid body to an extent which admits a safe division of the first two rings of the trachea. But it seems to have escaped his notice, while theorising on the operation, that a section of the cricoid cartilage must be *useless*, unless *abused;* that a rigid ring, divided at one point of its circumference, remains unloosened; that a single section of the cricoid cartilage could not be made available as a means for increased access to the air-tube, over and above that afforded by division of the trachea, except by employing on it a disruptive force, that should effect a counter-fracture at some other part of its circumference. Such violence on such an organ M. Boyer was far too judicious a surgeon to have sanctioned; and from the single instance, appended (p. 142 *bis*) to his speculations on the subject, it appears probable that the upward extension of his opening in the air-tube was useless; that an incision through the upper rings of the trachea sufficed for the escape of the foreign body; and that, in all essential particulars, the crico-tracheal operation is but tracheotomy at a higher than ordinary level, complicated with an unadvantageous and therefore objectionable intrusion on the larynx.

2. The *antero-inferior triangle* adjoins inwardly the space last described, is bounded outwardly by the decussation of the omo-hyoid muscle (which separates it from the superior compartment of the great anterior triangle) with the imaginary diagonal, which demarks it from the postero-inferior or supra-clavicular space. Its various parts and contents require some separate description. As regards the integuments, it will be remembered that the platysma only partly covers this space, and that the anterior jugular vein, when it exists, is contained here in the lower part of its course. The sterno-cleido-mastoideus follows the outer side of the triangle, but extend over it by its sternal border, so as to cover a large portion of its area. Beneath this muscle, the stronger deep layer of the cervical fascia is extended and splits internally to enclose the sterno-thyroideus, which likewise encroaches on the space by its inner side. Under this fascia the common carotid artery (beside which are the jugular vein and the pneumogastric nerve) ascends vertically, and is slightly overlapped from within by the thyroid body. The anatomy of the space is well developed, in considering the best mode of reaching the carotid artery: a vertical incision falling on the sterno-clavicular joint exposes the superficial fascia and part of the platysma; these being divided, the sheath of the sterno-mastoid is seen, and on its being opened the sternal fibres of the muscle present themselves, obliquely ascending outward: their division and displacement exposes the posterior layer of their fascial investment, which is here seen to ensheath the sterno-thyroid muscle: the descending branch of the lingual nerve (descendens noni) seems almost embedded in the deep layer of the aponeurosis, and reaches the outer edge of this muscle in the upper part of the space:—beneath the stratum of parts so constituted, the carotid lies with the associated organs: the jugular vein is on its outer side,

* In suggesting the possibility of injuring organs abnormally situated behind the trachea, the text particularly refers to the occasional passage of a right subclavian artery, from the left part of the arch, either between the œsophagus and trachea, or behind both those tubes. The anomaly is not a very rare one; and a case is reported, in which the artery, so running, was pierced by a bone, arrested in and perforating the œsophagus. (*Dublin Hospital Reports*, vol. ii.) The irregularities of the aorta itself, quoted by Tiedemann from Hommel and Malacarne, are of almost unique occurrence, hardly furnishing an additional argument for that uniform caution, which the above less infrequent abnormality makes imperative.

† Maladies Chirurgicales, vol. vii. p. 131.

the nervus vagus lies deeply between the two vessels and behind them; the cellular membrane, which invests and binds them together, appears to form an indistinct septum to isolate the artery; crossing the front of the sheath,—from the median line toward the jugular trunk, opposite which they pierce—are many veins, of which some are occasionally considerable in size: they are branches from the larynx, trachea, thyroid body, and sub-hyoid muscles, and among them, when it exists, must be counted the anterior jugular: they are capable of causing much inconvenience to the operator, and require to be carefully managed: on the left side, the internal jugular vein itself, inclining toward the median line below, slightly overlaps the artery: the posterior layer of the sheath of these vessels is a thin process of the fascia interposed between them and the sympathetic nerve, which descends vertically behind: separated in like manner from the great vessels, we find the inferior thyroid artery, which ascends in an obliquely serpentine course to the lower angle of the thyroid body, and the recurrent laryngeal nerve, mounting (on a plane deeper than that artery, internal to which it is situated) toward the posterior part of the cricoid cartilage; the nerve is therefore very nearly approached to the hindermost part of the tracheal cartilages, and, on the left side, ascends between them and the œsophagus, closely applied to the latter.*

The *thyroid body* belongs to this space by its lateral parts, and, when of moderate development, overlaps the carotid sheath. It consists of symmetrical lobular halves, united by the isthmus already alluded to: its lobes are pear-shaped, on a section, the small end being upward; they are plump outwardly where the fascia gives them a smooth envelope, but hollowed inwardly where they adapt themselves to the air-tube: the isthmus commonly connects the lobes by their lower part only, by overbridging the trachea at about its second and third rings: the apex of each lobe reaches to the ala of the thyroid cartilage, covering the fibres of the constrictor pharyngis, which arise there, and receiving the superior thyroid artery from the external carotid: the circumference of the organ presents, then, upward a crescentic sinus in which the angle of the thyroid cartilage, the crico-thyroid membrane and muscles, the cricoid cartilage, the first one, two or three rings of the trachea are seen: its thick outer margin,—running from the apex to the third, fourth, or fifth ring of the trachea—corresponds in that extent to the carotid artery, which it more or less overhangs, and below to the recurrent nerve of the larynx; by the extremity of this border the inferior artery reaches it from the thyroid axis; the inferior margin gives exit to veins, which have already been mentioned, and not infrequently receives by its middle a fifth artery from the arch of the aorta or from the arteria innominata.

From the remarkable vascularity of this body, so disproportionate to its volume and apparent unimportance in the œconomy, it readily falls into the heterogeneous group which the German anatomists have named "Blood-ganglia" (*blut-knoten*). From the same circumstance, and from the probably vicarious function which it seems to discharge, it is extremely liable to hypertrophy, the different forms of which, attended by whatever structural change, are confounded under the name of *goître* or *bronchocele*. From the account given of its anatomy, the symptoms of its enlargement may be surmised; for it is obvious that a tumour, so related to the windpipe and so checked in its outward growth by tense aponeuroses, must gravely affect respiration. Overlapping the common carotid arteries, the tumour derives from them a strong and often visible impulse; and, over and above the jerk, which they communicate to it, a general thrill of distensive pulsation, arising from its own almost erectile vascularity, may be felt by the surgeon. Superficial observation might fail to distinguish such a tumour from carotid aneurism, but anatomy establishes the diagnosis; for, in each movement of deglutition, the diseased mass accompanies the larynx, and is seen to rise and fall in the neck. Attempts at extirpating

* The *cardiac branches of the sympathetic*,—although they require notice in connexion with the anatomy of the large vessels,—have little particular interest in regard of the surgical operations, which are practised on these, and some account of them is therefore better appended in a note than blended with the text. They are seldom or never distinctly seen in operations; and the rule for their management is but a part of the general principle (which ought to be supreme in every surgical exposure of an artery, and the neglect of which has been, I doubt not, at the root of most unsuccessful issues) that the disturbance of surrounding parts, and the denudation of the artery, should both be in the very least degree, which will permit the ligature of the vessel to be accomplished. The cervical cord of the sympathetic lies, as already mentioned, behind the sheath of the cervical vessels, and presents three ganglia, from which, and from the cord, various branches originate. Of these ganglia,—the uppermost has often above an inch in length, is of tapering rounded form, and is situated in the posterior pharyngeal region, on the second and third vertebræ: the second, of smaller size and inconstant occurrence, usually lies upon the inferior thyroid artery: the third, frequently confused with the first dorsal ganglion, is deeply imbedded behind the origin of the vertebral artery. From these sources, assisted and reinforced by the pneumogastric and other nerves, the cardiac branches originate in a manner and succession which will be described in a future article. (See SYMPATHETIC NERVE.) In descending, they lie posterior to the sheath, and the superior one internally to it, close to the trachea, and, on the left side, to the œsophagus. When they approach the inlet of the thorax, they comport themselves variously in regard of the subclavian artery; sometimes passing behind it, on each side, and furnishing twigs, which cross its anterior surface; sometimes, on the contrary, crossing its front by their main branches; and sometimes so dividing as to envelop the artery in an abundant nervous plexus. They are very irregular; but, in all cases, largely communicate with the recurrent nerves, behind the subclavian arteries, and furnish numerous continuations, which descending around the three great vascular trunks to the arch of the aorta, hence prolong themselves to the base of the heart.

goîtres by the knife have been almost superseded by the discovery, that iodine exerts a marked controul over many enlargements of the thyroid body; and it would evince other boldness than that of knowledge, lightly to undertake the excision of a tumour so importantly connected. The jugular vein, the carotid artery, the pneumogastric nerve, which on each side the diseased body would overlap, —the trachea and œsophagus, which it would almost encircle, might indeed be avoided in an attempt at its removal; but the enormous venous as well as arterial hæmorrhage that must occur, and the extreme likelihood of dividing the recurrent nerves, would involve a not small possibility of accelerating the fatal result, and deter every prudent surgeon from attempting an operation of such extraordinary risk, except under circumstances that might justify the most favourable remote prognosis. The ligature of its nutrient arteries has been advocated as a cure for bronchocele; but, although this mode of procedure presents fewer anatomical difficulties than that last mentioned, yet, from surgical considerations of its extreme uncertainty and unsafe protraction, it seems little entitled to preference.

On the left side, the *œsophagus*, inclining from the median line, presents itself in the antero-inferior triangle. It only half emerges from behind the trachea (which still covers its right portion), and closely lies on the vertebræ: it continues the canal of the pharynx, from a line of abrupt distinction opposite the lower edge of the cricoid cartilage, downward. It is at its commencement that this tube most frequently interests the surgeon, by becoming the seat of stricture, or by arresting and fixing foreign bodies. To this space the operation of œsophagotomy belongs; and the left side is, for obvious reasons of convenience, chosen for its performance. In Mr. Arnott's instructive paper on the subject the following directions occur, which may serve to illustrate the anatomy of the region in regard of the operation in question: "The situation of the external incision will, in some measure, depend upon that of the body to be removed, but as the pharynx, tapering gradually in its descent, terminates in the œsophagus immediately under the larynx, it is here that a bulky substance is most apt to be detained. In reaching the œsophagus at this place, taking as a centre a spot corresponding to the level of the lower margin of the cricoid cartilage and the first ring of the trachea, the only parts of consequence, whose injury is to be dreaded, are the inferior thyroideal artery and recurrent nerve, (the superior thyroideal artery being too high to run any risk;) but these will not be wounded, if the same plan is adopted as that in the case related, of separating the deeper-seated parts by the handle of the scalpel and the finger instead of by the knife. Here they were not seen during the operation, in fact they were not within the sphere of the wound, for, on examining the parts after death, the artery and nerve were found below and on the inner side of it. Still I am satisfied by trials on the dead body, that the artery is likely to be divided if the operation is completed by the knife, and hence the expediency of proceeding deliberately, cutting but little at a time, sponging carefully, so as to see and avoid the artery, if possible, or to tie it immediately when cut. The recurrent nerve runs less risk as it reaches the side of the trachea, to which it is attached in its ascent, lower down. I do not allude to the carotid artery as being exposed to any peril. I think, with Mr. Allan Burns, that he must be wanton indeed in the use of his knife, who hurts this vessel. In making the incision into the œsophagus, it is to be remembered that the recurrent nerve runs in the angle between this tube and the trachea, and therefore the incision is to be made a little behind this angle." *

3. *Antero-superior triangle.*— This pretty nearly corresponds to the depression which in lean subjects is seen at the side of the neck beneath the jaw and in front of the sterno-cleido-mastoid muscle. It is bounded behind by the diagonal line to which we have so often referred; the posterior belly of the digastric and the superior belly of the omo-hyoid constitute, respectively, its upper and lower borders, and their convergence to the hyoid bone anteriorly forms its apex. The fascia superficialis, enclosing the platysma myoides, extends uninterruptedly over its borders; and the cervical aponeurosis splitting at each, extends singly over the area which they enclose: the transverse processes of the vertebræ, covered by muscular attachment and by the pre-vertebral aponeurosis, form its floor. The common carotid artery enters it below, and, at about the level of the lower border of the third vertebra, divides into the internal carotid, which continues to the cranium the direction of the trunk, and the external, which runs and ramifies in more superficial parts; the sympathetic, as in other regions of the neck, lies between the posterior layer of the sheath of the vessels and the pre-vertebral fascia; the superior laryngeal nerve lies in the same interval, obliquely bending from above to the posterior part of the thyro-hyoid membrane behind the vessels: it is on the confines of this triangle and the digastric space that the posterior belly of that muscle, accompanied by the stylo-hyoid muscle above and the lingual nerve below, arches across the external and internal carotids, and at about this level the stylo-glossus and stylo-pharyngeus with the glosso-pharyngeal nerve intervene between those large arteries. It is only below this crossing that the vessels fall under our present consideration, and their study may be facilitated by extending an arbitrary line of division from the os hyoides (at the apex of the space) transversely backward. Such a line would have below it the trunk, bifurcation and continuing branches of the common carotid, and the origin from the external of the superior thyroid artery alone; while, above the level referred to, the continued secondary trunks would be seen, and many of the branches

* Medico-Chirurgical Transactions, vol. xviii.

which spring from the external one, viz. the occipital passing obliquely toward the mastoid process, under cover of the posterior belly of the digastric, and hooked round by the hypoglossal nerve; the muscular, which is not invariably present, inclining outward to the sterno-mastoideus; the lingual and facial (divided by an imaginary prolongation of the cornu of the os hyoides from the superior thyroid) entering the digastric space, the former transversely by running along the cornu of the os hyoides between the hyo-glossus and middle constrictor, the latter more obliquely ascending; and the pharyngeal artery deeply running upward beside the pharynx. To all these branches a more particular description has been given in a previous article, than would be suitable to the present one; and to that the reader is referred for the details of their distribution. (See Carotid.) The jugular vein descends externally to the internal, as to the common carotid, the vagus lying, as in the lower region of the neck, between the two vessels and rather behind them. The vein receives several branches, in traversing this triangle, from the larynx and tongue, and usually the facial vein: all these, since they come from within, must cross in front of the artery, and sometimes form an intricate plexus, which much embarrasses an operator. In front of the sheath descends, with a slight inward obliquity, the branch of the lingual nerve, which at the lower part of the space, and while lying over the vein, forms a reversed arch of communication with the cervical plexus, whence branches are distributed to the subhyoid muscles. The integuments and platysma require no particular notice; their veins and nerves have already been described; among the former must be reckoned the anterior jugular; the space contains a great number of lymphatic glands, a long chain of which (*glandulæ concatenatæ*) lies along the outer side of the sheath of the vessels, while some also lie about the thyroid and lingual arteries on the inner side of the sheath. The surgical relations of this space are chiefly confined to the arteries: ligature of the common carotid or of either of its branches may easily be performed here, since the vessels lie under a much less thickness and variety of parts than below. A vertical incision falling on the point of intersection of the omo-hyoid and sterno-mastoid muscles, and successively dividing the superficial fascia (in which the platysma and cutaneous nerves are contained) and the cervical aponeurosis (a single layer, as it stretches across the space, but, of course, double where it encloses the sterno-mastoid,) exposes the sheath of the vessels, the veins which transversely cross its arterial portion, and the descendens noni which runs on the part of its wall corresponding to the jugular vein: and here, as he might open the sheath lower or higher, the surgeon would expose the common carotid or its branches; and, in remembering that the internal (so named from its distribution only) lies at first external to and behind the other, he would be able to isolate and secure either of these at his option. In any attempt to tie the branches of the external carotid, a clear notion of their respective relations to the hyoid bone is of indispensable necessity; and, in ascending toward the digastricus, it must be remembered that the lingual nerve crosses the carotid sheath but just below the border of that muscle, and that it and the facial vein are consequently exposed to injury. Attempts at suicide by cutting the throat seldom succeed; the incision is usually made closely either above or below the hyoid bone; in the former case entering the digastric regions, and dividing, with the muscles of the tongue, the lingual and perhaps the facial artery; in the latter case, traversing the thyrohyoid membrane, penetrating the pharynx, perhaps implicating the epiglottis, dividing the thyroid artery, and very rarely reaching the external carotid. The mode of searching for these vessels must vary according to circumstances, but, in all essential particulars, may readily be deduced from their anatomy.

4. The *postero-superior triangle* is a large space of singularly little interest, having its inferior boundary fixed by the omo-hyoid muscle, its anterior by the diagonal which intersects this, its posterior by the edge of the trapezius, and its apex by the mastoid process. It contains, below, a part of the brachial plexus (the anterior branches, namely, of the fifth and sixth cervical nerves, which directly pass beneath the omo-hyoid muscle into the adjoining inferior triangle,) the whole of the cervical plexus and many of its branches, the spinal accessory nerve, obliquely crossing from the sterno-mastoid to the trapezius, which it enters near its clavicular insertion, and some ramifications from the arteria transversalis colli, which, under the name of superficial cervical, ascend in the space, supply its cellular membrane and lymphatic glands, and ultimately inosculate with descending twigs from the occipital. The pre-vertebral fascia covers its deep parts; the common cervical extends between its borders; the platysma myoides exists as a covering for it only in its lower part.

5. The *postero-inferior triangle*, (that of the subclavian artery,) is one of manifold importance. The well-known lines of the omo-hyoid and clavicle limit its area above and below, the former dividing it from the space last considered, the latter from the pectoral region; intersecting the omo-hyoid, our imaginary diagonal, as it stretches from the centre of the sterno-clavicular joint upward and outward, bounds it internally, and constitutes an arbitrary but most useful separation between the space, exclusively appropriated to the subclavian artery with its branches and that internally adjoining it, (the antero-inferior,) which is the proper territory of the carotid. The parts forming its deep or posterior wall are, the transverse processes of the lower cervical vertebræ and head of the first rib, the outer edge of the longus colli and the broad lower part of the scalenus posticus: its inferior wall presents the upper surface of the first rib, and within the curve of this bone a part of the upper inlet of the

thorax, at which during life the pleura bulgingly rises, deriving considerable support from the horizontal infixion of the cervico-thoracic fascial septum. Externally to the curve of the rib, (with the coracoid process bounding it outwardly, the clavicle in front, and the superior costa of the scapula behind,) is the space through which vessels and nerves connect the cervical and axillary regions; to the borders of which, deep layers of aponeuroses are so fixed that the regions only communicate in the line of the vessels, within the infundibulum of prevertebral fascia. Its anterior or covering wall presents, in addition to the platysma and subcutaneous areolar tissue, which in all directions extend beyond its margins, the cervical fascia, as a single layer (except where it splits at the trapezius and sterno-mastoid) fixed to the clavicle below, and enclosing the omo-hyoid above. From the higher part of its posterior wall, originating at the anterior tubercles of the transverse processes, descends the scalenus anticus to fix itself in the floor of the space, on the upper surface of the rib, anteriorly. It intercepts, like a flying buttress, a space between itself and the posterior wall, occupied by the brachial plexus and subclavian artery, round all which, as also round the subclavian vein, which lies in front of the scalenus, the prevertebral aponeurosis is folded and prolongs itself as a funnel; it is from this, that the slip of fascia is derived, which passes to the clavicle, in the manner described above, as a horizontal process, dividing the axilla from the neck.

As the distributive anatomy of the vessels and nerves will be detailed in a future article, (*vide* Spinal Nerves, Subclavian Artery), their arrangement will now be only sketched, in its regard to surgical relations. The many important points of distinction between the right and left sides of the body in this region will presently be considered, the description meanwhile applying to both indifferently. The subclavian artery, from the sterno-clavicular joint outward, over-arches the floor of this region, presenting upwards a convexity in the interspace of the scaleni, downwards a concavity, which adapts itself to the pleura and to the rib. It gives off, as from an axis, branches from the four cardinal points of its circumference: 1. downwards the internal mammary, which, crossed at its origin by the phrenic nerve, descends within the cartilages of the ribs; 2. upwards the vertebral, which, after a course of an inch between the scalenus anticus and longus colli, enters the canal of the transverse processes, usually at the sixth; 3. forwards the thyroid axis, a short trunk giving origin to the inferior thyroid branch (already seen obliquely ascending behind the carotid sheath), the ascending cervical, which mounts beside the phrenic nerve, along the scalenus anticus, and two transverse branches, which direct themselves outwardly, crossing that muscle,—the transversalis humeri along the clavicle, the transversalis colli higher, amid the branches of the brachial plexus and winding round the scalenus posticus to gain the inner edge of the scapula; lastly, 4. backwards an artery, which, directing itself to the neck of the rib, subdivides there into two branches, one of which descends across the rib to the thorax, the superior intercostal, while the other continues, between the neck of the rib and the seventh cervical transverse process, the backward direction of the common trunk, and then ascends among the deep muscles of the dorsal region—the arteria cervicalis profunda. The course of the subclavian artery is conveniently divided into three stages; a last or distal one, in which after having passed behind the scalenus anticus, it has, behind it, the scalenus posticus, below it the groove of the rib, above it (extending likewise a little behind) the brachial plexus of nerves, in front of it the coverings of the space we are considering, a familiar knowledge of which is here especially needed, since it is in this portion of its course that the artery is usually tied for axillary aneurism: a second stage, in which it lies between the scaleni, its convexity toward their origin from which the brachial plexus divides it, its concavity reposing on the pleura; and a first or tracheal portion of its course, differently related on the two sides of the body, but thus far alike in both, that from it the branches originate, that its concavity is to the pleura and its convexity, almost at right angles to the direction of the carotid, looks upward; that it is related, behind, to the sympathetic and to the last cervical transverse process,—in front, to the vagus and phrenic nerves and to the jugular and subclavian veins,—inwardly to the carotid artery. The circumstances of difference are mainly due to the fact, that, while on the right side a common brachio-cephalic trunk exists—the arteria innominata,—which lies at no great depth from the sternum, so that its branches diverge to their respective destinations from a comparatively superficial and single point, behind the sterno-clavicular joint; on the left side, contrarily, the carotid and subclavian arise separately from the arch, the latter, at a vast depth from the surface, actually beside the vertebræ; with the exception of having a thoracic commencement (nearly corresponding to the tracheal *half* of the arteria innominata), the left carotid can scarcely be said to differ importantly from the right, at least in virtue of its own course; it is somewhat deeper, lies in front of the œsophagus from the inclination of that tube, has the thoracic duct ascending at its outer side, and is, as will be explained directly, overlapped by the jugular vein in the lower part of the neck. The subclavian artery on the right side passes from its origin almost transversely to the scalene space, covered by the muscles which have been enumerated, crossed at right angles by the phrenic and pneumo-gastric nerves and by the jugular vein; the left subclavian, on the other hand, reaches the groove on the rib after a very deep and a very oblique course; it can scarcely be said to have any transverse direction, but gradually, by an inclination outwards and forwards, approaches the rib during its ascent, so that, if traced toward its origin from the tracheal edge of the scaleni, it would appear, instead of having, as its fellow has, a certain length of transverse course, to bend abruptly toward the arch of the aorta, becoming deeper and deeper; or, in other words, while the right subclavian has a considerable extent at its highest level, from the sterno-clavicular joint to the scalene space, the left has comparatively but a culminating point, to which it suddenly rises and from which it quickly sinks. Thus the nerves, which cross the course of the right, are nearly parallel to that of the left: and the relation of the jugular vein is similarly changed, while the subclavian vein, having a longer course than on the right side, obliquely crosses the thoracic portion of its artery.

The anatomy of the veins requires some separate notice: in crossing the scalenus anticus at its insertion, the *subclavian vein* is, on both sides, anterior to the artery, from which the tendon divides it, and somewhat inferior to it; the *jugular vein* in the upper part of the neck descends as already mentioned, beside the internal and common carotid arteries, to which it is external, similarly on both sides. The union of these veins, however, to form the venæ innominatæ differs in the following manner. On the right side, the jugular vein, inclining from its artery below, joins the subclavian on the insertion of the scalenus anticus: the arrangement of these important parts is such that they form together an elongated triangle, of which the carotid artery is the inner side, the jugular vein the outer, and the first stage of the subclavian the base, here crossed at a right angle by the pneumogastric nerve, (which reflects its recurrent branch upward and inward behind the artery,) and more outwardly by the phrenic: from this point of junction the innominata vein runs toward the pericardium on the pulmonic side of its artery, that is, externally to it and on an inferior plane. On the opposite side the jugular vein, anticipating its ultimate destination, obliquely bends toward the right side, overlapping the carotid artery, in front of which it receives the subclavian vein by its outer side: the resulting vena innominata sinistra runs almost transversely across the arch to join its fellow at the right extremity of this. The vertebral vein opens into the innominata, just internally to the confluence which forms that trunk. On the left side it crosses the subclavian artery: on the right side it is usually, though not always, behind it.

The *thoracic duct*, mounting from the mediastinum, passes behind the arch, emerges between the carotid and subclavian arteries in the root of the neck, and, curving abruptly downwards, outwards, and forwards, crosses the latter artery and discharges its contents by a valvular opening into the subclavian vein close to the angle of its confluence with the jugular.

The surgical relations of this region regard the subclavian artery and the operations which are practised on it. Of these the most usual is its ligature on the outside of the scalene space, where lying upon the upper surface of the rib. An incision, corresponding to the middle of the clavicle, through the skin, superficial fascia, and platysma, and through the strong single layer of cervical aponeurosis which is fixed to the bone,—extending, if necessary, to the origin of the sterno-mastoid and to its sheath, with careful avoidance of the external jugular vein, here bending round the outer edge of the muscle,—opens a space, wherein loose cellular tissue alone veils the continuation of the pre-vertebral fascia, which is prolonging itself from the scaleni around the subclavian vessels: a division of this lamina, as near as possible to the costal attachment of the scalenus anticus, completes the exposure of the artery, which is recognised by the finger, as it emerges from behind the tendon of that muscle, in immediate contact with the rib. The steps of the operation thus considered seem of no great difficulty, and are, in fact, so long as the parts retain their normal bearings, of extremely easy performance: the artery is at an inconsiderable depth; its relations are singularly definite and unembarrassed. But such is not their practical facility, under circumstances which necessitate the operation. To tie the subclavian artery for axillary aneurism may be one of the most difficult operations in surgery, involving extreme patience and much manual skill in him who undertakes it; for the disease, as it extends, not only fills the axilla, but encroaches on the neck, thrusting up the clavicle, and obliterating the interval between that bone and the omo-hyoid muscle. The operation might almost be compared to one of tying the axillary artery in its normal relations from above the clavicle. It lies at the bottom of a deep and narrow cavity, in which the operator must be guided entirely by the sense of touch, and can only apply this under the disadvantage of distance. The circumstances of such a case are well given by the late Mr. Todd of Dublin,* who states that, "so much was the relation of parts altered by the magnitude of the tumour and consequent elevation of the clavicle, that the omo-hyoid was situated an inch below this bone, and it was found necessary to draw it up from its concealment, and to cut it across, that the subjacent parts might become accessible." It must be under the influence of such changes that the aneurismal sac, by encroaching on the very seat of the operation, becomes liable to injury, and may, as I have witnessed, be actually transfixed by the needle. The relation of the brachial plexus is commonly such that it lies on a plane posterior to the artery, and for the greater part above it; occasionally, however, its last root passes in front of the vessel, and in the disguised condition of parts is not readily to be distinguished from it; since the touch fails in its ordinary discrimination, where exercised with so much difficulty, and it is hardly practicable to apply the test of compression to the supposed arterial trunk, in the view of ascertaining its relation to the tumour, without unintentionally extending the same pressure to the subjacent artery and mis-informing one's-

* Dublin Hospital Reports, vol. iii.

self accordingly. It must have been through these means of fallacy that I have seen a most cautious and experienced operator deceived: he compressed the supposed artery, raised on the aneurism-needle, with his finger; the pulsation ceased, the ligature was tightened, and the severe pain occasioned by this step at once declared the error (which was in the course of a few moments remedied, and the operation ultimately and entirely successful); the convexity of the needle was doubtlessly resting on the artery, and compressed it upon the surface of the rib.

The application of a ligature to the subclavian artery on the tracheal side of the scaleni presents, perhaps, fewer merely mechanical difficulties than that just described, but involves a disturbance of more important organs, and requires perfect acquaintance with their anatomy. A separation of the sterno-cleido-mastoideus from its inferior attachment, and a division of the sterno-hyoid and sterno-thyroid muscles and of their sheaths (including that deep layer which lies beneath the sterno-thyroideus and immediately covers the vessel) will expose the artery.* The jugular vein is seen crossing it, close to the scalenus, at the outer part of the wound, behind which lies the phrenic nerve; at the inner part of the wound the bifurcation of the arteria innominata is brought into view, and the subclavian is seen diverging from the carotid. Between this point and the border of the jugular vein, from half an inch to an inch of artery intervenes, about midway on which the nervus vagus crosses at a right angle. If the nerve require to be drawn aside, this manœuvre must be executed with the extremest delicacy and gentleness;† and the operator should not fail to remember his dangerous proximity to the pleura. The view of these parts is obscured by considerable venous hæmorrhage, which is here especially inconvenient, from the imperative necessity which exists for clearly seeing the artery and ascertaining the position of its branches before making any attempt to pass the needle. It is considered desirable to apply the ligature on the inner side of the vertebral branch, and as near to it as possible: yet, even under the most favourable circumstances, the adhesive actions at the seat of ligature must be seriously disturbed, both by the near direct stream of the carotid, and by the recurrent tides of the vertebral, mammary, and thyroid arteries. The single intance, in which I have seen this rare operation performed, was by my friend, Mr. Partridge, who brought to bear on its execution a perfect familiarity with every actual relation, and with every possible contingency; nor could it have been confidently undertaken, or safely conducted, by one of inferior resources. The case was in so far favourable, that the tumour was small, the position of parts unaltered, the arteries regular and free from disease, and the venous hæmorrhage not so troublesome as in many cases it certainly would be; the parts were clearly seen, and the artery secured without the least unnecessary disturbance of contiguous parts. Yet, I confess the impression, which I derived from this single instance of operation, and from frequent consideration of the parts in a great variety of subjects, to have been, that ligature of the arteria innominata would in all cases be as easy, and, in many, far easier to perform, would (by involving organs of less delicacy and importance, than those interested in the tracheal ligature of the subclavian) render hæmorrhage a less embarrassing obstacle, and would afford a better prospect of undisturbed adhesion in the artery. The steps, necessary for exposing the one, require so little modification, to become equally adapted for the other, that the surgeon might even be determined in his choice of either, by considerations developing themselves during the operation, by greater or smaller branchless extent of the subclavian artery, by the vertebral vein obscuring a large portion of this, or by other circumstances of the kind.

Although the *arteria innominata* cannot in anatomical strictness be considered as belonging to the neck, yet, in regard both of disease and of surgical operation, its affinity to that region is so close as to warrant its mention in this place. It rises from the convexity of the arch of the aorta, just as that main vessel, having terminated its ascent, inclines leftward. This point is in young subjects the highest level to which the aorta attains; but, as Cruveilhier notices, in old age the extreme part of the arch, which corresponds to the origin of the left subclavian artery, is higher. In early life, too, from incomplete development of the sternum, the convexity of the arch more nearly

* The description in the text is confined to the mode of tying the *right* subclavian artery, on which alone, as yet, the operation has been performed. As regards the left, the course of the vagus and phrenic nerves (which run parallel to the vessel), and of the thoracic duct (which almost surrounds it) would enormously multiply the risks of the operation; and the increasing depth and oblique descent of the artery, as traced from the scalenus inwardly, would, it is believed, defeat every endeavour to effect its adequate exposure. Should it be desirable to secure the vessel internally to its passage over the rib, the most available method would probably be that of tying it in the scalene space. This operation was performed in a single instance by Dupuytren in 1819 with success. The section of the scalenus anticus, if it were carefully executed, would be less perilous than on the right side, and might, under favourable circumstances, afford a sufficient space, between the branches of the artery and the aneurismal sac, to admit the safe application of a ligature. A complete division of the clavicular origin of the sterno-cleido-mastoideus would be required; and it would be necessary to obtain a distinct view of the phrenic nerve, before cutting the scalenus: the internal mammary artery might, as M. Malgaigne remarks, be injured even more readily than the nerve, if this incision were carelessly extended toward the median line.

† It is difficult, in reading the record, or in witnessing the progress of unsuccessful cases of operation at this part of the neck, to avoid believing that a neglect of cautious tenderness in managing the pneumogastric nerve, has tended to compromise the safety of the patient. No surgeon, who considers its vital importance to the functions and nutrition of the lung, can avoid viewing any unnecessary disturbance or rude traction of it as eminently perilous.

approaches the root of the neck than in adult growth, and, as also the branches arising from it, may more easily be endangered in tracheotomy and other operations in the neighbourhood. Its length is somewhat above an inch: its direction obliquely upward and outward, toward the sterno-clavicular joint, opposite to which it divides. In this course it corresponds, behind, to the trachea,—in front to the sternum, from which the remains of the thymus gland, the origin of the sterno-hyoid and sterno-thyroid muscles, and (close to its origin) the transverse crossing of the left vena innominata separate it,—externally, to its accompanying vein, and, mediately, to the pleura,—internally, to the left carotid from which it is separated by a triangular interval in which the thymus, or its remnant, lies upon the trachea.

The frequency of its undue extension beyond the precise limit assigned to it, and consequent appearance in the sub-hyoid region of the neck, together with the fact of its often furnishing a middle inferior thyroid artery, are contingencies never to be disregarded in operations thereabout.

This artery has now been tied for cure of aneurism at least six times; unsuccessfully—it is true—but with such nearness to success as not to forbid cautious repetition. The mode of procedure adopted by Dr. Mott consisted in a transverse division of the skin, muscles, and fasciæ along the edge of the clavicle and sternum,—in raising these, and taking the subclavian and carotid arteries (which he seems to have denuded to some extent) as guides to the innominata, in drawing the jugular vein, the vagus, phrenic and recurrent nerves outwards, in pressing the pleura carefully downwards with the convexity of the needle, while he carried its point from below upwards around the vessel.

6. *The digastric space* is bounded below by the curve of the digastric muscle, and extends above within the angle and horizontal ramus of the jaw, so that, if considered as a triangle, it may be described as having its base represented by the internal oblique (or myloid) ridge of the lower jaw, and an imaginary prolongation of this to the root of the mastoid process,—its anterior border formed by the ascending belly of the digastric muscle,—its posterior by the descending fibres of the same; and its apex will obviously be at the point of their reflexion by the hyoid bone. The skin, the superficial fascia with the platysma, and the cervical aponeurosis, wall it in, and that part of the inferior maxilla which lies beneath the oblique line, to the basial edge of which the fascia adheres, overhangs it; its deep surface is constituted by the mylohyoid muscle and by the side of the tongue and pharynx in front, by the vaginal and styloid processes of the temporal bone behind. A fibrous slip, reflected outwardly from the styloid process to the angle of the jaw, and to the deep surface of the aponeurosis, distinctly divides the digastric space into two parts. Of these, the *posterior* is the smaller; its vertical extent is to the temporo-maxillary articulation: backwards it is bounded by the auditory canal and mastoid process; inwardly, by the vaginal plate, the styloid process and its muscles. In the anterior direction the border of the jaw, together with the septum just described, are its limits: whence it seems, within the neck of the jaw, to prolong itself as an interspace between the attachments of the pterygoid muscles.

Between the unyielding walls of this narrow space, the *parotid gland* contracts itself into a wedge-like form, reaches in the one direction to the styloid process and is folded round it, in the other is prolonged with the maxillary vessels between the insertions of the pterygoidei. In its substance the external carotid ascends to its terminal subdivision,—the portio dura curves from the stylo-mastoid foramen, and breaks into the lash of communicating branches, known as *pes anserinus*,—the roots of the external jugular vein unite to assume that name,—and junctions of the portio dura with the superficial temporal nerve, and with the auricular branch of the cervical plexus, are met with. Its remarkable impaction behind the jaw is probably designed for affecting its function by the mechanical stimulus of the masticatory movements. Its enlargement may inconveniently hinder these motions, and, where accompanied by much induration, actually lock the jaw. The merely anatomical difficulties of extirpating the parotid gland have probably been somewhat over-rated; but cases requiring the operation must be of exceeding rareness. Absorbent glands lie on many points of its surface, and in its substance; their enlargement is frequent, and has been mistaken, in several instances, for an affection of the parotid itself.

The arteries met with in this space are all branches of the external carotid: the occipital and auricular follow its posterior border, the latter usually traversing a part of the gland; the temporal artery emerges at the upper, the transverse facial at the anterior edge of the parotid, while from its deep portion the internal maxillary passes forward, within the neck of the jaw, toward the zygomatic fossa.

The *anterior* division of the digastric space considerably exceeds the posterior in size: its vertical extent behind is from the curve of the digastric up to the outward surface of the buccal mucous membrane, where reflected from the molar alveoli to the side of the tongue; but anteriorly it seems to be limited by the lower surface of the mylo-hyoid muscle, and so to be shallower; though, in reality, this is not the case, for the muscle referred to merely forms a partial septum, dividing the shallow and superficial part, just mentioned, from a deeper, sublingual portion of great importance. The anterior division of the digastric space may accordingly be considered as bounded above by the mucous membrane of the mouth in its reflexion from the oblique line of the jaw to the border of the tongue, in an extent reaching from the base of the coronoid process to the symphysis; and, internally, by the side of the tongue, (presenting the muscular substance of the genio-hyoideus, genio-hyoglossus, hyoglossus, and stylo-glossus,) and by that of the pharynx. It is only in front that the mylo-hyoid muscle, as a partial septum, divides a superficial space from the general submucous tract; and it is necessary to understand this arrangement, in order to apprehend the mode in which the submaxillary gland approaches the mucous membrane of the mouth: the gland lies in the superficial division of the space, and it is round the posterior edge of the mylo-hyoid muscle that its duct is reflected in proceeding to discharge itself, which by so entering the sublingual space it is enabled to do. The anterior division of the digastric space contains, superficially the gland just mentioned, the facial artery and vein with some of their branches, the mylo-hyoid twig from the third division of the fifth, and many lymphatic ganglia. The gland receives a thin capsular investment from the deep surface of the fascia, closing the space, and this prolongation contracts and condenses itself round the posterior extremity and duct, accompanying these in their turn round the mylo-hyoid, and furnishing the duct with a dense fibrous tunic. The artery enters the space from below, by passing beneath the posterior belly of the digastric muscle, very tortuously winds through the submaxillary gland, and bends over the basial edge of the jaw a little in front of the masseter. It furnishes a deep ascending branch (the tonsillary) near the angle of the jaw and many glandular twigs; but its only considerable branch in this region is the sub-mental, which runs toward the median line just beneath the jaw, and, supplying the mylo-hyoid muscle on which it is applied, and the anterior belly of the digastric, terminates by freely communicating with its fellow. The sub-mental branch derives additional importance from the frequency of an anomalous distribution, by which, piercing the mylo-hyoid muscle and entering the sublingual space, it partly discharges the functions of the lingual artery in supplying the sublingual gland. The facial vein lies behind the artery, and quits the space below in passing over the digastric and stylo-hyoid muscles, which divide it from the artery. Its usual or chief termination is in the internal jugular; but it frequently contributes more or less to form the external or the anterior jugular vein. The mylo-hyoid nerve runs parallel to the origin of the muscle, which gives it its name, and supplies it and the anterior belly of the digastric. The lymphatic glands are numerous and important: they receive the absorbent vessels from the face and likewise from the mouth and pharynx, are the frequent seat of strumous inflammation, readily sympathize in disordered conditions of the fauces and alveoli, and take an active part in propagating the malignant influence of cancerous ulcerations on the face. These parts are all covered in by the aponeurosis,—which fixes itself to the base of the jaw,—and by the platysma and superficial fascia,—which continue themselves on the face. They are readily accessible to the surgeon, but seldom subjected to any operation of importance. The deep or sublingual portion of the digastric space has its roof formed by the mucous membrane, which, between the tongue and alveolar arch, constitutes the floor of the mouth: the side of the tongue and the continuous surface of the pharynx, as already described, compose its inner wall; and it follows from the previous description that, in part at least, the mylo-hyoid is its floor. The gustatory nerve runs through it beneath the mucous membrane, which it supplies: the hypo-glossal, describing a parallel but inferior curve, is distributed in succession to the muscles of the inner wall of the space; the glosso-pharyngeal between these two in height, but confined to the root of the tongue, bends inwardly beneath the stylo-glossus; the lingual artery, emerging from under cover of the hyo-glossus, which has hidden its tortuous ascent, divides anteriorly into two branches; a ranine, which follows the curved border of the tongue to its tip, where it archingly unites with its fellow; a sublingual, which directing itself a little outward, supplies the third salivary gland: this little body lies on the divergent fibres of the genio-glossus, near their origin, and close beneath the membrane of the mouth: finally, the duct of the submaxillary gland, traversing the space obliquely, crosses its contents, and communicates with the cavity of the mouth just beside the frœnum. This space is the seat of ranula (a tumour formed by obstruction of the submaxillary duct), and of some salivary concretions; in both which complaints the distended canal is brought so immediately beneath the mucous membrane, which it raises, that other parts are little liable to injury: here, too, it is that the surgeon, when obliged to divide the frœnum linguæ, must cautiously cut the too tight fold near to the symphysis, and vertically, lest, in extending his incision backward, he should wound the ranine artery. Sharp instruments penetrating downward beside the tongue may wound the sublingual artery, and the consequent hæmorrhage, distending the submucous space, raise the reflected membrane on each side into swellings of such size, as to suggest imminent peril of suffocation.*

7. The small region to which, under the name of *posterior pharyngeal*, I propose giving brief notice, has for its roof the basilar portion of the occiput and petrous part of the temporal bone, and presents in this direction the orifices of the jugular, carotid, and anterior condylic canals: it extends downwards between the pharynx and vertebræ into the anterior triangle of the neck, and is separated from the posterior division of the digastric space, within which it lies, by the styloid and vaginal processes, and by the attachment to these of a strong layer of fascia, which passes beneath the digastric muscle. The internal carotid artery, surrounded by branches from the superior cervical ganglion,

* Such an accident I have seen arise from the inadvertent thrust of a tobacco-pipe; the swelling was very considerable on both sides, and produced alarming distress. Cold (aided, no doubt, by the pressure of the effused blood) succeeded in staying the hæmorrhage; had this not been the case, it would have been necessary to expose the lingual artery on the cornu of the os hyoides and to secure it; or, had its ligature not sufficed, likewise to tie the adjoining trunk of the facial, from which the sublingual branch is occasionally derived.

ascends here; and since, from the angle of the jaw to the base of the skull, it lies beside the pharynx, covered by the lateral parts of that cylinder, it is liable to be involved in a punctured wound from the mouth; and this unfortunate accident has not unfrequently occurred in operations on the tonsil, which organ in its swollen state is so closely applied to the internal carotid artery, that if it were transfixed by a bistoury in an outward direction, the vessel could hardly escape. Hence the importance of care, in relieving tonsillary abscesses, to direct the point of the instrument, as much as possible, towards the median line, and to select for incision that part of the cyst which most nearly adjoins the palate. The jugular vein emerges behind the artery and runs downwardly along its outer side: of the three divisions of the eighth nerve, which leave the cranium in front of the vein, the glosso-pharyngeal is applied to the outer, the vagus and spinal accessary to the inner part of its circumference. The muscular branch of the latter winds from within behind the vein, and obliquely descends to the sterno-mastoid: the vagus continues to descend vertically along its inner side, but both the glosso-pharyngeal and hypo-glossal nerves obliquely cross between it and the artery, and subsequently arch over the latter in their passage to the tongue. From its relations to the vertebræ in this space, the pharynx may participate in their diseased conditions, and give vent to abscesses, dependent on caries of the cervical spine. The surgeon may sometimes assist his diagnosis of complaints so situated, by introducing his finger into the pharynx.*

8. Lastly, I proceed to recapitulate, briefly and in connexion, the practical relations of the *sterno-cleido-mastoideus* in regard of the spaces which have been described. Its clavicular origin is in the inferior division of the posterior triangle, covers the subclavian artery in the first and second portions of its course, and in many instances extends this origin so far outwardly as to hide the vessel during a considerable part of its third stage; it likewise, of course, covers many parts lying between it and the artery,—the jugular and subclavian veins, the vagus and phrenic nerves, the scalenus anticus and omo-hyoid muscles, and the origin and divergence of many arterial branches: these fibres obviously require division, varying according to circumstances, when the subclavian artery is to be exposed. The interval between its origins corresponds to the sterno-clavicular joint, and, on the right side, to the bifurcation of the arteria innominata: along the cellular line, prolonged from this interval, (which answers to the diagonal dividing the two great triangles,) M. Sedillot proposes to penetrate, without section of muscular fibre, in order to reach the common carotid artery. The sternal head of the muscle, directing itself backward, obliquely crosses, in the inferior segment of the great anterior triangle, the sheath of the vessels, from which the sub-hyoid muscles partly divide it. In order to reach the common carotid artery these fibres are accordingly cut asunder, except where the operator prefers the anatomical *finesse* of M. Sedillot's plan. Tracing the muscle in the middle of the neck, we find it a most serviceable guide in operations on the common carotid, and on its primary or secondary branches. A vertical incision directed to the point of its intersection with the omo-hyoid muscle (nearly opposite the cricoid cartilage) enables the surgeon conveniently to draw these muscles aside, and to expose, according as the wound is higher or lower, the external and internal carotids, or the trunk from which they originate, and, in close connexion with the anterior layer of their sheath, the descending branch of the hypo-glossal. Finally, about and above the level of the hyoid bone, the anterior edge of the sterno-mastoid, with the posterior belly of the digastric, and the cornu of the os hyoides, furnish definite marks for discovering the superior thyroid, the lingual, the facial or the continued external carotid artery; since, in the space so bounded, the last named vessel vertically ascends, the first almost horizontally advances, and the other two pass to their destinations with intermediate obliquity.

* A case has lately occurred to the writer illustrating this fact. It was one of neuralgia; the pain was of extreme severity and obstinacy; it affected the occipital region, and was referred to the great occipital nerve. An examination through the pharynx succeeded in detecting, as its probable cause, a firm (apparently bony) tumour, connected with the transverse processes, between which that nerve emerges.

IV.—ADDITIONAL PRACTICAL OBSERVATIONS.

It yet remains, in conclusion, briefly to review some circumstances in the anatomy of the neck, which particularly bear on its diseases and on the operations undertaken for their cure. 1. In endeavouring to form a *diagnosis of tumours* in this region, the surgeon will, in the first place, remember their extreme liability to deceptive pulsation, and will neglect no precaution for ascertaining their relation to the large arterial trunks. The glands, which lie about the common and external carotid arteries, in the anterior triangle of the neck, and those which are situated in the supra-clavicular space, are particularly subject, when enlarged, to derive pulsation from the vessels to which they are respectively contiguous. The history of the case,—the signs afforded by auscultation,—the manner in which a non-aneurismal tumour may frequently be moved away from the artery that communicates an impulse to it,—the marked difference even to the unpractised hand, between the mere jerk of elevation in the one case, and the thrilling diastole in the other, are materials for distinction, to which it is here enough to allude. Nor must it be forgotten, that, from the nearness of the aortic arch to the root of the neck, its aneurisms, as they grow upwards and clear the strait of the thorax, may simulate the characters of a like disease in the carotid or subclavian artery. Cases constantly occur, (and may be found abundantly quoted in systematic surgical works,) in which tumours of this kind, rising in the vicinity of the sterno-clavicular articulation, have been mistaken for aneurisms of the innominata, on the one side, or of the carotid or subclavian on the other, according as they have, in their growth, deviated right or left from the median line. Burns records a case, in which an aneurism so originating from the aorta, was even falsely attributed to the right subclavian: it bulged first on the acromial side of the sterno-mastoid muscle, "a point, where no one would expect a tumour to present, which had worked its way from within the chest."* This is an extreme and rare instance; but not so are the misapprehensions, previously alluded to: it is certain, and matter of frequent experience, that aneurisms of the arch, where they escape from the resisting stricture of the sternum and clavicles, project so abruptly, as to have the appearance of belonging to the artery, over which their fundus is situated. They frequently have (as in the case which Burns quotes from Sir Astley Cooper) a Florence-flask-like form, the neck of which may be narrow, and the fundus high in the neck. In several such cases the deception has been so complete, as to suggest to the surgeon the propriety of tying the common carotid below its supposed aneurism:† but no instance is on record, as I believe, of the adoption of so calamitous a proceeding. It is, indeed, true and almost self-evident that an aneurismal swelling, formed at the root of the carotid, will commonly first be perceived in the small interval between the heads of the sterno-mastoid, and, in its further growth, may displace these, or cause their absorption:—that one connected with the arteria innominata is likely to project nearer to the trachea, and on the inner side of the sterno-mastoid:—that one originating from the subclavian will usually rise on the outer side of the same muscle; and that the force of the pulse is generally diminished in the branches of a trunk affected with aneurism:‡ yet, while such facts may have their weight, as excluding certain tumours from the respective categories of subclavian, carotid, or innominata aneurism, and as so assisting the negative diagnosis of these diseases,—it admits of no doubt that they are insufficient to establish grounds for positive recognition. The aortic aneurism may imitate every circumstance of position in the neck, which has been mentioned; and can hardly fail by its abnormal pressure to affect the circulation through the contiguous artery, and to weaken the pulse of its branches. To other criteria, than the mere symptom of external prominence, the cautious surgeon will look for a safe diagnosis of swellings in the root of the neck. The minutest inquiry into the history of the patient during the period, which preceded any outward projection of the tumour, and into the actual state of his thoracic organs and of their functions (with notice of every pain, palpitation, or dyspnœa),—an observation of any existing impediment to the return of blood, as evidenced by venous congestion,*— and complete and careful stethoscopy, are all requisite to that *study of the particular case*, which alone can justify an opinion.

* Op. cit. p. 62 et seq.

‡ Vide Cyclopædia of Surgery, vol. i. p. 237.

2. An important subject for mention, in regard to the surgical anatomy of the neck, is the provision for *collateral circulation*, when the main trunks are obliterated. Mr. Burns, in discussing the question of tying the arteria innominata, speaks of these natural resources in the spirit of confidence, which has been familiar to English surgery, since the time of its profound lawgiver, John Hunter: "We entertained no dread of the circulation being supported in the right arm; nay, we reduced it to a demonstration. On the dead subject, I tied the arteria innominata with two ligatures, and cut across the vessel in the space between them, without hurting any of the surrounding vessels. Afterwards, even coarse injection impelled into the aorta, passed freely by the anastomosing vessels into the arteries of the right arm, filling them and all the vessels of the head completely." The fluid passed (as the blood would, under similar circumstances, pass in the living subject) from the carotid of the left side to that of the right, through the mesial inosculations of the thyroid, lingual, facial, temporal, occipital, and (not least) cerebral arteries: from the left subclavian, in like manner, chiefly through the thyroid and vertebral branches; and thus a regurgitant stream would flow into the main vessels, up to the very site of ligature. Partly through the continued trunk of the tied vessel, so reinforced by its fellow, and partly by secondary communications (as of the occipital with the cervicalis profunda, of the facial with the internal maxillary, of the pharyngeal and palatine arteries) the blood is distributed in its legitimate destination. If the subclavian alone be obliterated at its commencement, the inferior thyroid and vertebral (communicating with their fellows, but still more largely with the carotid of the same side) helped by the muscular branches of the occipital, will convey the derived current. If the ligature have been applied beyond the scaleni, the transverse branches of the thyroid axis, by their free inosculations with the articular branches of the axillary, and with its subsca-

* An interesting case is given by Professor Pattison, in his Appendix to the edition of Burns, (on the Surgical Anatomy of the Head and Neck,) from which I have already quoted. A person who had suffered during six months with obscure pains about the lower region of the neck, which were attributed to rheumatism, died comatose. It was found on dissection that there arose from above the arteria innominata a large tumour, which projected forwards, adhering to the sternum, which its pressure had rendered carious; and that "the transverse vein, formed by the union of the left subclavian and jugular veins, presented a very uncommon appearance. It had more the character of a ligamentous cord than of a distended vessel; and when opened, it was found filled with coagulable lymph, which completely obliterated its cavity. On being traced downwards towards the right auricle, the vein was seen to terminate at the sternal aspect of the aneurismal tumour, that portion of it which crossed the tumour having from pressure become obliterated."

pular branch, abundantly restore the circulation. Should the carotid have been tied, its mesial communications, already mentioned, especially those within the skull, and about the thyroid gland,—assisted at those places and elsewhere by anastomoses with the subclavian,—adequately fulfil their vicarious duty. So abundant are these various communications, that the ligature of a main trunk, in the dead subject, in no degree interferes with the distension of its branches by fine injection: if we inject water, or any equally fluid material, through one carotid artery, it freely returns by the other. Under these circumstances, it excites our surprise that the cure of aneurism by ligature should be so certain; for the amount of circulation through the affected vessel can at first be little affected, and the arrest and ultimate cure of the disease must be referred rather to the withdrawal of a distensive impulse than to any considerable derivation of current. It seems to have been considered, in operating for aneurism, that, so long as no large branch arose from the vessel closely on the cardiac side of the ligature, it mattered not what branches might arise on its distal side,—how large, or how near. In many instances secondary hæmorrhage, inducing death, has manifestly depended on defective adhesion at the distal side of the ligature, and for an obvious reason. The condition of that part of the artery has been neglected: it has been thought unimportant though a large vessel should arise just beyond the ligature; or, if a great length of artery have been injudiciously denuded, the cardiac portion has had an exclusive preference of security given to it, by the ligature being drawn as high as possible in that direction. If an equal attention were bestowed on both sides of the proposed seat of ligature,—if like care were taken, in both directions, to avoid the likelihood of disturbance to the adhesive process by side currents,—if, where the artery has been much denuded, (instead of a single thread being applied at the cardiac extremity of that isolated portion, by which plan the succeeding part of the tube,—though separated from its connexions, and likely to ulcerate or slough,—is yet left open to the stream of recurrent blood,) a second ligature were placed at the distal limit of the endangered part, there would seem no greater reason to anticipate the occurrence of secondary hæmorrhage than when arteries are tied after an amputation.

3. *Anomalous arrangement* of the cervical vessels is a contingency which the surgeon must bear in mind Most of these are comprehended in the abnormalities of the arch already described. (See AORTA.) The existence of a median inferior thyroid artery, derived from the arch, or from the arteria innominata;—the irregular passage of the right subclavian artery from the left side, behind the œsophagus, or between that tube and the trachea;—an early division of the carotid, even to nearly the level of the sternum, or so late a one, that the common trunk furnishes many, or most, of the branches normally originating from the external;—the absence of an arteria innominata, its branches arising separately from the arch, or in irregular combination with those of the left side; the occasional origin of the vertebral from the common carotid,* are the deviations which it most behoves the practitioner to remember.

4. Certain *veins* in the neck have an anatomical disposition, rendering them liable, when opened in surgical operations, to become channels for inspiration of air to the cavities of the heart, the fatal tendency of which is well known. The internal jugular, innominatæ, and subclavian veins are, as M. Bérard notices, "at the root of the neck, so firmly united by fascial laminæ and cords to the adjacent bones and muscles, that they do not collapse on division, but gape:" and it is obvious that this circumstance (but for which they would be flattened, and rendered impervious, by the atmospheric pressure on their outward surface) must expose them remarkably (perhaps alone) to a dangerous participation in the *inhaustive* movements of breathing. M. Velpeau (who has written a paper of excellent critical research on the subject†) recommends the following precautions in approaching veins of the nature described *(veines canalisées)*: studiously to avoid wounding them,—to detach no deeply fixed tumour from its adhesions, without having previously commanded the vessels at its base,—and to maintain no unnecessary tension on the fasciæ, by forced positions of the shoulder.

For the BIBLIOGRAPHY see that of ANATOMY (INTRODUCTION), and the references under the various articles referred to. One work may be particularized, as belonging to the region, and as having, more than any book of the age, given an impetus to the study of anatomy in that most practical form, which interests the surgeon by unfolding the relations of disease and of operative measures. Through the happy combination referred to, the mere barren description of regions has become *surgical anatomy*; and to Dr. Colles of Dublin, and Allan Burns of Glasgow, belongs the merit of having, first in this country, illustrated that natural connexion, which gives to anatomy the interest of application, and to practice the security of knowledge.

(John Simon.)

NERVOUS SYSTEM.—In proportion as our knowledge of the intimate texture of animal and vegetable organisms advances, the doctrine gains ground that many of the phenomena, called vital, are to be attributed to the special endowments of distinct forms of animal or vegetable matter; distinct as regards their anatomical characters as well as their chemical composition; distinct, therefore, as

* A single instance has occurred to me in the dissecting-room, of an arrangement, which I believe to be very rare. An innominata (for so its origin and course entitled it to be named) divided at the sterno-clavicular joint into common carotid and *vertebral*: the right subclavian arose from the descending part of the arch, and directed itself to the scalene space by passing behind the œsophagus.

† Médecine Opératoire; and Lettre sur l'Introduction de l'Air dans les Veines. Paris, 1838.

regards their physical properties; and, as appears not unreasonable to conclude, capable of manifesting a distinct series of vital forces.

If great strength and power of resistance be requisite, a particular form of animal matter (gelatine) is united with an earthy material to constitute bone; for the developement of strength, combined with elasticity or flexibility, this same kind of animal matter, or a modification of it, is again employed, containing none or a very slight proportion of earthy material, and forming the various kinds of cartilage and ligament; but for the play of the active powers of life—for the developement of living movements—whether in the performance of the nutritive functions, in growth and reproduction, or in the display of muscular force and activity, two substances, the most complex in chemical constitution of any in the body, and possessing the greatest atomic weight, are made use of to form the structures, on which these remarkable phenomena depend, namely, *muscle* and *nerve*. These structures are composed respectively of fibrine and albumen; they are organized in analogous forms, and by their mutual reactions they exhibit the marvellous effects which animal power is capable of producing.

GENERAL OBSERVATIONS ON THE DISPOSITION AND COMPOSITION OF THE NERVOUS MATTER, THE NATURE OF NERVOUS ACTIONS, AND THE SUBDIVISIONS OF THE NERVOUS SYSTEM.

The nervous matter presents the singular peculiarity that it alone, of all the varied forms of animal texture, is directly influenced by the mental acts of animals. It is that part of the organism through the immediate agency of which mind operates upon body and body upon mind. Through this connexion with the psychical principle of the animal, sensation is produced, and volition is enabled to exercise its influence on muscular organs. And in the whole range of the mysterious phenomena, which the student of nature meets with, there is nothing so inscrutable as the fact that the workings of the mind can disturb and impair the organization of the nervous matter; or, on the other hand, that the disorganization of the nervous matter is capable of deranging mental manifestations.

The existence of this remarkable and peculiar kind of organic matter is limited to the animal kingdom, and is therefore one of the characteristic features of animals as distinguished from plants. It is obviously the presence of a psychical agent controlling and directing certain bodily acts of animals, which has called into existence the particular apparatus which the nervous matter is employed to form.

In the largest proportion of the animal kingdom, the nervous matter is so disposed or arranged as to form a system complete in itself, and distinct from, although connected with, the other textures and organs. This is called the NERVOUS SYSTEM—the developement of which has always a direct relation to the bodily organization and psychical endowments of the animal.

The nervous matter is accumulated into masses, forming what are denominated CENTRES of nervous actions; and it is also developed in the form of fibres, filaments, or minute threads, which, when bound together, constitute the NERVES. The latter are *internuncial* in their office; they establish a communication between the nervous centres and the various parts of the body, and vice versâ; they conduct the impulses of the centres to the periphery, and carry the impressions made upon the peripheral nervous ramifications to the centres. Nor are the nerves mere passive instruments in the performance of their functions; but produce their proper effects through their susceptibility to undergo molecular change under the influence of appropriate stimuli.

The centres are the great sources of nervous power; they are the laboratories in which the nervous force is generated. The mind appears to be more immediately connected with one of them, which, pre-eminent on that account, exerts a certain control or influence over its fellows.

In the centres there are two kinds of nervous matter, distinguished by certain anatomical characters and by certain physiological properties and uses. The one is globular or vesicular in structure, grey in colour—*dynamic* as regards office. The other is fibrous, its fibres being tubes containing nervous matter; it is white in colour, and is devoted to act as a *conductor* of impulses to and from the grey matter. The white matter is that of which the nerves are composed, and the two kinds of matter do not occur together any where but in the nervous centres; in fact, their co-existence in any part of the nervous system is sufficient to constitute that part a centre of nervous action.

In the lowest creatures the existence of nervous matter is as yet problematical. It is supposed by some physiologists that it is diffused in a molecular form throughout the body of the animal, and the muscular tissue being likewise disposed in a similar way, the one may act upon the other at every point. Were this supposition true, it might be further conjectured that, under such circumstances, only one kind of nervous matter, *the dynamic*, would exist; for as the office of the white nervous matter is chiefly to propagate or conduct to distant parts the changes which originate in the grey matter, the former would not be required in animals, in which the elements of the grey matter are in contact with those of the other textures at every part of the body.

The form in which nervous matter first developes itself as a distinct tissue is in that of threads or cords, into the composition of which areolar tissue and bloodvessels generally enter. The class of animals in which this arrangement prevails has been designated by Mr. Owen *Nematoneura;* and, in many of these at least, the existence and the disposition of grey matter have yet to be ascertained.

The nervous matter of both kinds is a substance of extreme softness and delicacy, liable to break up under the least pressure; the nervous tissue owes much of its physical tenacity to the other tissues which are associated with it, and to the numerous bloodvessels which play among its elements.

The chemical composition of this matter has been an object of investigation with several observers, but it is remarkable that few comparative analyses of the two kinds of nervous matter have been made with a view to determine on what the differences between them depend; and, indeed, such an analytical investigation is as yet a great desideratum. The part which has chiefly been selected for analysis is the brain, in which doubtless both kinds of nervous matter were indiscriminately examined.

Among the earliest investigations of this kind were those of Leming; some time afterwards Thouret examined the brain; and still later Fourcroy. The last writer notices the large admixture of water with the cerebral substance, and points it out as one of those animal substances in which water exists in the largest proportion; from constituting, as it does, three-fourths or four-fifths, and in many instances seven-eighths of its weight. Vauquelin's analysis, made in 1812, gave a considerable insight into the true composition of the brain. This chemist showed that the cerebral substance is an emulsive mixture of albumen, fatty matter, and of water, the last holding in solution certain saline and other ingredients common to the brain with other parts of the body. By solution in boiling alcohol, Vauquelin was enabled to obtain the two constituents of the fatty substance, namely, the elaine and stearine (margarine). Vauquelin also recognised the presence of phosphorus in the brain. His analysis yielded the following result:—

Albumen		7.00
Cerebral fat	stearine . . 4 53 / elaine. . . . 0.70	5.23
Phosphorus		1.50
Osmazome		1.12
Acids, salts, sulphur		5 15
Water		80.00
		100.00

John, who specially analysed the grey nervous matter, states that it is deficient in fatty matter, and that its albumen is less tenacious than that of the white. And Lassaigne states that the grey substance is deficient in white fatty matter, but contains a greater proportion of red, 3.7 per cent. being the amount contained in the grey, and 0.9 per cent. in the white.*

Vauquelin remarks that the medulla oblongata and the medulla spinalis have the same composition as the brain, but contain a much greater quantity of cerebral fat, with less albumen, osmazome, and water.

M. Couerbe's elaborate analysis does not appear to be entitled to much confidence, since the compounds into which he resolved the cerebral matter did not, on analysis, always present the same composition. This variation of elementary constitution he attributed to physiological differences in individuals.

The latest and apparently the most complete analysis of the brain is that by Fremy, published in the Annales de Chimie for 1841. In the main his results agree with those of Vauquelin.

He states that the cerebral mass is formed, as had been already shown by Vauquelin, of an albuminous matter containing a great quantity of water, and which is found mixed with a peculiar fatty matter; and that these different substances exist in the following proportions, seven parts of albumen, five parts of fatty matter, and eighty parts of water.

The chemical examination of the albuminous matter yields nothing of importance. This substance is insoluble in water, in alcohol, and in ether. M. Fremy's principal care has been to determine the composition of the fatty matter, and this he has endeavoured to do by an analysis of the brain in different animals, but principally in man.

His method of proceeding is, to cut the brain into small pieces, and to treat it with successive portions of boiling alcohol, leaving them for some days in contact with the spirit. The object of this is to remove from it its large quantity of water, which interferes with the action of ether upon it. The coagulated mass thus obtained is submitted to pressure, is divided rapidly in a mortar, and is then treated by ether, first cold and subsequently hot; the resulting fluids when submitted to distillation yield a viscid residue, which is called the ethereal product.

The principles which he extracts from the brain by this method, are—1. a white substance called *cerebric acid;* 2. cholesterine; 3. a peculiar fatty acid called *oleophosphoric;* 4. traces of elaine, margarine, and fatty acids. These principles are not always found in an isolated state; for the cerebric acid is often combined with soda or phosphate of lime; and the oleophosphoric acid is commonly found in the state of a salt of soda.

Cerebric acid, when purified, is white, and is in the form of crystalline grains. It dissolves without residue in boiling alcohol, is almost insoluble in cold ether, more soluble in boiling ether. It has the remarkable property of swelling up, like starch, in boiling water, but appears to be insoluble in that liquid. It enters into fusion at a high temperature, approaching closely that at which it is decomposed, and is combustible. It contains no sulphur, but some phosphorus. The result of its analysis by Fremy is 66.7 per cent. of carbon, 10.6 of hydrogen, 2.3 of nitrogen, 0.9 of phosphorus, 19.5 of oxygen.

Oleophosphoric acid is separated from cerebric acid by its solubility in ether. It is still accompanied by elaine and cholesterine, which are withdrawn from it by alcohol and ether. This acid is of a viscid consistence, insoluble in cold alcohol, but dissolving readily in boiling alcohol; it is insoluble in ether. Placed

* Valentin Repert. 1837, p. 186.

in contact with soda, potass, and ammonia, it immediately gives soapy compounds. It forms compounds insoluble in water with other bases. M. Fremy has observed a remarkable transformation of oleo-phosphoric acid. When boiled for a long time in water or alcohol, it gradually loses its viscidity and becomes a fluid oil, which is pure elaine, while the liquor contains phosphoric acid. This decomposition becomes very rapid, when the liquor is rendered slightly acid. Although M. Fremy's attempts to form this acid directly, by uniting elaine and phosphoric acid, were unsuccessful, he still deems it probable that this acid may consist of the elements in question and be analogous to the compound of sulphuric acid and elaine, or sulph-oleic acid. It contains from 1.9 to 2 per cent. of phosphorus in the condition of phosphoric acid.

M. Fremy also finds, as Couerbe had previously done, that cholesterine may be extracted from the brain in considerable quantity. He obtains it by boiling the ethereal product in alcohol rendered strongly alkaline by potass. A cerebrate, an oleate, and a phosphate of potass are thus obtained, with glycerine and cholesterine. On cooling, the alcohol deposits the cerebrate and phosphate of potass and the cholesterine; and in treating the deposit by cold ether, we remove all the cholesterine, which may be purified by subsequent crystallizations.

In preparations of the brain, preserved in spirits, a substance of crystalline character, which resembles cholesterine, is apt to form round the piece.

The quantity of phosphorus varies considerably in different periods of life, and is greatly diminished in idiotcy. The following table from some analyses of L'Heritié will illustrate this statement.

	Infants.	Youth.	Adults.	Old Men.	Idiots.
Albumen	7.00	10.20	9.40	8.65	8.40
Cerebral fat	3.45	5.30	6.10	4.32	5.00
Phosphorus	0.80	1.65	1.80	1.00	0.85
Osmazome and salts	5.96	8.59	10.19	12.18	14.82
Water	82.79	74.26	72.51	73.85	70.93
	100.00	100 00	100.00	100.00	100.00

From these comparative analyses it appears that the *minimum* of phosphorus exists in infancy, in idiotcy, and in old age; and that the *maximum* of water is found in the infant. This latter fact is of practical interest, and affords some explanation of the greater tendency to liquid effusions in early childhood than in more advanced life.

Nervous actions.—In order to offer a clear explanation of the working of the nervous system, it will not be amiss to quote a few examples of actions effected through its instrumentality.

Let me, however, first remark, that as the mind is connected more especially with the nervous system, so that system becomes the channel of its mandates, as well as of impressions conveyed to it. But there can be no doubt that the nervous system can act independently of the mind, and that certain actions which need the intervention of nerves and nervous centres, are accomplished without the consciousness of the individual, and sometimes in spite of his Will.

It seems, therefore, a correct, as it is certainly a convenient arrangement of nervous acts, to divide them into those in which the mind is concerned, either as an agent or as a recipient, *(mental nervous acts,)* and into those which result from mere modifications in the nervous matter, quite independent of mental interference *(physical nervous acts)*.

Let me illustrate this division by examples. Any ordinary act of the will, the voluntary movement of the arm for instance, is effected by a mechanism to which the first impulse is given by a change in the mind; I will to move my arm; this mental change affects the nerves of the arm, which excite certain muscles to act. That the nerves are the channels for conveying this influence of the will is proved, beyond all doubt, by experiment and disease. If their continuity with the brain be injured, the power is necessarily lost, although the will itself continue unimpaired.

We *feel* through the instrumentality of the nerves. In writing, I am conscious, through the sensibility of my fingers, that I hold a pen in my hand. Were that sensibility destroyed, although the power of holding the pen remained, I should lose the consciousness of its presence between my fingers, and they would cease to grasp it. This sensibility is due to the communication of the nerves with the brain, for any solution of continuity destroys it; nor can any part be said to be *sensible* or to possess *sensibility* which does not communicate with the brain through the nerves. And various parts differ as regards the *degree* of sensibility which they enjoy, according to the number of nerves distributed to them, and perhaps also according to the manner in which the nerves are connected with them. A touch on the skin covering the olecranon is scarcely felt, whilst the finest point impinging with the slightest force on the skin of the tip of the finger is instantly perceived.

Sensations differ in *kind* as well as in *degree*. The power by which we are made sensible of contact, or by which, under the influence of undue stimulation, we become conscious of pain, is called *common sensibility*. Doubtless nearly all textures possess this to a certain degree. Tendon and cartilage enjoy a very much less amount of it than skin and muscle. But we can also appreciate the influence of light, of sound, of odor, of flavour, and we are enabled to do this by means of particular nerves. This power is that of *special sensibility*. The nerves, which convey these impressions of special sensation to the mind, are incapable of responding in any other way, even to a mechanical stimulus. When the retina is stimulated with the point of a needle, the sensation of a flash of light is produced: when the auditory nerve is excited by a mechanical impulse upon the tympanum, sound is heard.

The mechanism (so to speak) of sensations of whatever kind is exactly in the reverse direction to that of voluntary motions. In the latter the change begins in the mind and ends in the body; in the former the impression is made first on the body and is conveyed to the mind. In both cases mental change, whether active or passive, is necessarily associated with the nervous act.

There are other actions in which the mind is concerned, although the *will* does not take any share in them. These are, such as may be produced under the influence of those sudden, momentary, and involuntary mental changes, which are called *emotions*, and which may be excited, either by an impression conveyed to the mind from some external cause, through the senses, or by some change in the mind itself, arising in the train of its thoughts. Who has not felt the thrill which pervades every part of the frame, in listening to some harrowing tale of woe? or, when the imagination, in its musings, conjures up before the mental vision some fearful scene of lamentation and wretchedness? How keenly do the emotions of joy and sorrow, anger and pity, cause themselves to be felt at every point of the system. The blush of shame, the pale curling lip of anger, "the eye in a fine frenzy rolling," are all examples of the emotions of the mind influencing bodily actions. The changes which the countenance undergoes in accordance with varying states of the mind result from the same cause. The will may acquire the power of controlling to a great extent this influence of emotion upon the expression of the features; but to attain this faculty in great perfection requires great strength of will and frequency of exercise. Few men ever acquired such controul over the play of the features, and such power of resisting the influence of emotion as well as of imitating that influence, as Garrick and Talleyrand.

The power of the emotions over the nervous system is shewn not merely in those actions which the will may controul, but also in others, which, as being in no degree voluntary, and therefore in a great measure disconnected from the animal functions, have been called *organic*. Upon none of these does emotion exert more influence than upon the circulation. In blushing, in the deadly paleness of the blood-deserted cheek, in the cold sweat of fear, in the depression of the heart from syncope, we find unequivocal instances of actions of an involuntary kind, produced by this influence. Many of the sensations which are felt in grief, fear, anxiety, or in the paroxysm of hysteria, are in a great measure due to local changes in the capillary circulation caused by the power of emotion over it. It would seem that there is no part of the nervous system which mental emotion may not reach; and no fact is of more general application than this, to the explanation of the multifarious forms of morbid sensation.

Of the physical nervous actions.—When the eyelid is raised so as to admit light suddenly to the bottom of the eye, the pupil instantly contracts, nor is the individual conscious of the change which is taking place in it, and he is equally unable to controul or prevent it. The degree of contraction appears to be proportionate to the intensity of the stimulus.

When a morsel of food is applied to the isthmus faucium, an action of deglutition is instantly induced. The palato-pharyngei muscles and the constrictors of the pharynx are immediately brought into play. This action is entirely involuntary, and cannot be controlled by the power of the will; it may be brought on even in the state of coma, when the individual is insensible to any external impression, and the fact is one of practical application, as shewing how persons in that state may be made to swallow by bringing the morsel into contact with the mucous membrane of the pharynx. Moreover it is an action which the will cannot imitate unless there be something to be swallowed. If the fauces be completely clear of any solid or fluid, this action cannot be performed; to call it into play, we instinctively bring mucus or saliva to the region of the fauces, and that stimulus brings about the required action. We have here, then, an instance of an action, which may take place despite of the will, which the will cannot imitate, which may be produced when consciousness and will are in abeyance: it is, therefore, an action independent of the mind's influence, and which may fairly be ascribed to a cause purely physical.

The sudden application of cold to the surface of the body or to any part of it, more especially to the face, causes an immediate and involuntary excitement of the muscles of respiration, and may be quoted as an instance of an action of similar kind to those mentioned in preceding paragraphs. The will may control this action to a limited extent, but never entirely.

A large number of movements in the living body, and especially of those which are commonly called organic, might be referred to as examples of physical nervous actions, in which the stimulus acts independently of the mind. These actions may be produced by a physical change taking place in the nervous centre and propagated directly to the muscular texture of the part (the moving power), as in the case of convulsive movements produced by irritant diseases of a nervous centre; but the ordinary manner in which they are effected is by the application of a stimulus to a surface. Through afferent nerves this stimulus affects the nervous centre, and produces a change there, which excites certain other nerves proceeding from that centre to the organ in which the movement occurs. To take, as an example, the act of deglutition above referred to. The morsel of food stimulates certain nerves, *the* *glosso-pharyngeal*, which are freely distributed upon the mucous surface of the pharynx. This stimulus causes a change in the medulla oblongata, in which those nerves are implanted, and that change is propagated thence by the *pharyngeal branches of the vagus* to the muscles which contract the pharynx in the act of deglutition.

In such an action the change in the nerves by which the muscular contraction is excited must take place in a two-fold direction,—*first*, from the circumference to the centre, from the point of application of the stimulus to that at which the nerves become implanted in the centre; and, *secondly*, from centre to circumference, from the point at which the stimulus falls upon the centre to that where the nervous fibres mingle themselves with the muscles of the part to be moved. The stimulus, which is *incident* upon the nervous centre, is said to be *reflected* by it to the muscular textures, the immediate agents of the required movement. Hence Dr. Marshall Hall has proposed to distinguish a special system of *incident* and *reflex* nerves, or of *excito-motory* nerves, the former being *excitor*, the latter *motor*. This distinction, considered anatomically, is as yet quite hypothetical, for we have no unequivocal proof that the nerves of sensation and volition, which in their ordinary mode of action are *afferent* and *efferent* as regards the brain, may not be competent by the relation which they must necessarily bear to the spinal cord, to perform the actions which are thus assigned to a distinct system. The determination of this point depends more upon the solution of certain problems respecting the anatomical constitution of the nervous centres, than upon any purely physiological experiments. It will be made the subject of careful examination at a subsequent part of this article.

The great peculiarity of this class of nervous actions is their *independence of the mind*. An act of the mind forms no *necessary* part of their mechanism. At the same time there are certain of them which do not take place without the mind being conscious of the change. The act of deglutition above referred to, although quite independent of the mind, does not generally take place without being *felt*. But the change in the pupil, consequent upon the stimulus of light acting through reflex nerves upon the iris, is not at all perceived by the individual, and is therefore in every respect independent of mental change. Let it be remembered, then, that there are some physical nervous actions which the mind is not conscious of, and others of which the mind will always, or at least generally, take cognizance.

We may conclude this brief reference to nervous actions by the following classification of them:—

Psychical or mental nervous actions:—

Actions of perception.
Actions of emotion.
Actions of volition.

Physical nervous actions:—

Actions from a physical change originating in the nervous centre; as in disease.

Reflex actions—
a, with consciousness.
b, without consciousness.

Anatomical subdivision of the nervous system.—The nervous centres, as they are found in the Vertebrate series, are distinguished as the brain, or encephalon, the spinal cord *(medulla spinalis)*, the ganglions. In the Invertebrata, the centres all bear the anatomical characters of ganglions, although, doubtless, they present some analogy in office to those specially distinguished among Vertebrata. Their arrangement varies considerably according to the differences of form of the various invertebrate classes.

The brain and spinal cord, and the system of nerves connected with them, constitute *the cerebro-spinal* portion of the nervous system, which Bichat distinguished as *the nervous system of animal life*, a distinction which, as it was dependent on his untenable hypothesis *of the two lives*, ought now to be discarded. The only subdivision of the nervous system which can be conveniently adopted must rest upon the basis of anatomy. There is not a sufficient distinctness of function in different portions of the nervous system to justify the separation of them on physiological grounds.

There are very numerous ganglions connected with the *cerebro-spinal* system. These are the ganglions on the posterior roots of spinal nerves, the ganglion of the fifth pair, those of the glosso-pharyngeal, and of the vagus. They are conveniently distinguished as *cerebro-spinal ganglions*.

A large portion of the nervous system is made up entirely of ganglions, with their connecting cords and nerves, which ramify in a plexiform manner among various internal viscera and upon the coats of bloodvessels. In the vertebrated animals, where it is highly developed, it is disposed as a chain of ganglia on each side of the spine, and at the base of the skull, near the foramina, through which the spinal and encephalic nerves pass out; and at all these situations it forms a very intimate connexion with the nerves of the brain and spinal cord.

This portion of the nervous system exhibits many peculiarities referable to its composition, its mode of arrangement, and its connexion with the organs among which its nerves ramify, which, at least, entitle it to be considered apart from the cerebro-spinal system; and many go so far as to affirm its entire independence of that system, and to assign to it a peculiar action, different from that of the nerves connected with the brain and spinal cord. Bichat calls it *the nervous system of organic life*. Previous to his time it was known as *the great intercostal nerve (nervus intercostalis), the great sympathetic nerve (nervus sympathicus magnus)*, and now it is very commonly described under the latter name. The term *visceral nerve* has also been proposed for it. It has also been distinguished as the *ganglionic system*. It is difficult to find an unexceptionable name for it which does not involve the adoption of some theory respecting its function. On the whole, the terms *sympathetic nerve* and *ganglionic system* are those which appear liable to fewest objections, although by no means free from them, and they will be employed in the course of this article.

Such are the only subdivisions of the nervous system which anatomy appears to warrant. Others have been proposed; but as they are founded upon physiological opinions which are as yet hypothetical, it is unnecessary to discuss them at present.

Having thus given a brief and general account of the nervous system and of nervous matter, we proceed to consider the anatomy and physiology of this system under the following divisions:—I. The general anatomy of nerves. II. The comparative anatomy of the nervous system or its disposition throughout the animal kingdom. III. The anatomy of the nervous centres, the ganglia, brain, and spinal cord. IV. and lastly, the office of the nervous system and the functions of its various parts.

NERVE.—(*νευρον, nervus;* Germ. *nerve;* Fr. *nerf.*) The nerves perform the *internuncial* office in the nervous system by maintaining communications between the various organs and tissues and the nervous centres. They are bundles of threads of various size, surrounded by sheaths of membrane, with more or less of areolar tissue interposed.

The nerves of the cerebro-spinal system and of the great sympathetic exhibit such different characters as regards their anatomy, that they may be examined separately.

Cerebro-spinal nerves.—In examining a cerebro-spinal nerve, we find it invested by a sheath of membrane, which has adherent to its inner surface thin layers of areolar tissue which pass, like so many partitions, between the threads or fibres of which the nerve is composed. This sheath is commonly called the *neurilemma;* it is analogous to the sheath which surrounds muscles. Its office is chiefly mechanical, namely, that of binding the constituent fibrillæ and fascicles of the nerve together, so as to protect them and to support the delicate plexus of capillary bloodvessels from which they derive their nutriment.

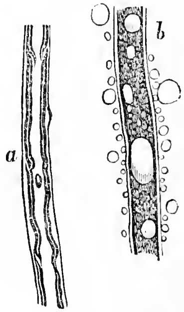
The neurilemma is composed of fibres of the white fibrous kind. It exhibits to the naked eye the appearance of a fibrous membrane, white and almost silvery; and its microscopic characters are those of the white fibrous element, although not presenting much appearance of wavy fibres. The fibres are, for the most part, parallel to the axis of the nerve; but there are some which cross the nerve at right angles, or appear to pass spirally round it. The septa between the secondary bundles of the nerves seem to consist of a less perfect fibrous tissue, containing the remains of numerous cytoblasts. A yellow fibrous tissue of the finest kind exists here in very small quantity.

The bloodvessels are distributed upon the external investing sheath and upon the septa. In some of the large nerves, the sciatic for example, these may be often seen minutely injected with blood. They are disposed somewhat similarly to those of muscles, running parallel to the fibres and fascicles of the nerve. The capillaries are among the smallest in the body: they form oblong meshes of considerable length, completed at long intervals by vessels which cross the fibres of the nerve more or less in the transverse direction. Henle assigns to them, when empty, a diameter not exceeding $\frac{1}{6000}$th of an inch. These bloodvessels are generally derived from neighbouring arterial branches; sometimes a special vessel accompanies a nervous trunk, and even perforates it, passing along its central axis, as is well known to descriptive anatomists in the sciatic and the optic nerves.

After the external part of the neurilemma has been dissected off, the nerve may be torn by needles and divided into secondary bundles and fibres. The ultimate fibre can then be readily distinguished by the aid of the microscope, from its being incapable of further subdivision by mechanical means; and an accurate knowledge of its structure is of the utmost importance to the formation of correct opinions respecting the actions of the nervous system.

The ultimate (or, as it is also called, the primitive) nervous fibre, is a tube composed of a fine transparent homogeneous membrane, in a great degree resembling the *sarcolemma* of muscle. It is elastic, like that membrane, perfectly homogeneous, and, according to Schwann, in young nerves has the nuclei of cells connected with it. It may be called the *tubular membrane* of nerve (*a, fig.* 329). The contents of this tube consist in a soft, semifluid, whitish, pulpy substance, which is readily pressed out of its cut extremity. In the nerve that is quite fresh, having been taken from an animal just dead, this pulpy matter is quite transparent and apparently homogeneous. The tube membrane presents the appearance of a delicate line, resem-

Fig. 329.



Nerve tubes altered by re-agents.

a, tube altered by water. The light external line is the tubular membrane; the dark inner double-edged one, broken here and there, is the white substance of Schwann. *b*, shows the change produced by the action of ether on the nerve-tube of the common eel; several oil globules have coalesced in the interior, and others have accumulated around the exterior of the tube.

bling, when perfectly fresh and unaltered by re-agents, the margin of an oil globule. When the nerve-tube has been treated with water, or has been allowed to remain a little time on a piece of glass, we observe within the tubular membrane a double-edged layer of a whitish material of different refracting power from either that which occupies the centre of the nerve-tube or the tubular membrane itself. The later after death the nerve is examined, the more distinct does this inner layer become. The addition of water, alcohol, and other re-agents always renders it more evident, and seems to destroy the apparent homogeneousness of the pulpy contents of the nerve tube. This layer within the tubular membrane is that which, according to Schwann, gives to the nerve-tubes their white colour; it is therefore called by him *the white substance.* Within this and occupying the centre of the tube is a transparent, somewhat flattened, band, which is extremely delicate, and in which it seems impossible to recognize any more definite structure.

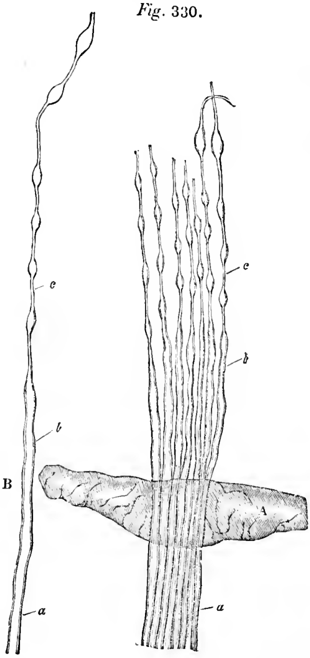
Thus Remak and others describe three distinct parts in the nerve fibre:—1, the outer investing membrane, *tubular membrane;* 2, an inner layer of membrane (*the white substance* of Schwann) lying immediately within the first; 3, a central substance of nervous matter, called *flattened band* by Remak, and supposed by him to consist of several filaments, or the *axis-cylinder* of Rosenthal and Purkinje.

It is evident that the contained matter of the nerve-tube is extremely soft: it yields under very slight pressure, and may be readily made to pass from one part of the tube to another. When pressed out of the nerve tube, it is apt to assume the appearance and form of globules varying in shape and size, which are easily distinguished from the true nervous globules by the absence of nucleus. Firm pressure will also completely empty the tubular membrane, and thus afford us a good opportunity of examining its structure, which has always appeared to present the same homogeneousness as the *sarcolemma* of muscles to which we have compared it. Some observers, however, admit a complexity of structure in this tubular membrane; an appearance of longitudinal fibres has been noticed by Valentin and Rosenthal, and the former describes a fibrous arrangement, as of oblique fibres winding in opposite directions, surrounding the tube.*

The addition of water causes the contents of the tubular membrane to separate from the inner surface of the tube, owing to a shrivelling or coagulation which it excites in the nervous pulp. Alcohol produces a similar effect, but occasions a more perfect coagulation of the soft nervous matter; and it is particularly worthy of observation, that the complication of structure remarked by various observers and above described, in the tubular membrane as well as in its contents, is never seen in the perfectly fresh nerve, but is always rendered visible by keeping or by the influence of various re-agents. And this fact may well excite a doubt as to the reality of the complex structure of the nerve-tube, as described in the preceding paragraphs.

In a word, the real structure of the primitive nerve fibre appears to be a tube composed of homogeneous membrane, containing a delicate, soft, pulpy, semi-fluid and transparent medulla or nervous substance, which is readily disturbed by manipulation, and altered by the addition of the simplest substances—even water. The tubes when quite fresh are perfectly cylindrical; but pressure or separation alters them in shape likewise, probably by disturbing the position of the nervous matter, pushing more than is natural into one part, and consequently diminishing the bulk of the contents of another part: the latter will consequently collapse, and the former become enlarged, distended, and even varicose. (*Fig.* 330.) The margins of nerve-tubes that have been separated, for this reason constantly appear wavy, and at other times distinct swellings or enlargements form in the course of the fibre, separated by constricted portions. These swellings sometimes occupy one side of the tube only: in shape they are globular or ovoidal, and more frequently involve the whole tube; they exist at irregular intervals

Fig. 330.



A, Nerve tubes becoming varicose at their entrance into the spinal cord. At *a*, *b*, *c* the gradual diminution of the thickness of the wall is seen. B, a single nerve tube, cylindrical at one part, varicose in the rest. (From Valentin.)

* The spiral arrangement of fibres described by Barry is attributed by him to the membranous layer which forms within the tubular membrane, the white substance of Schwann.

from each other, and are extremely variable in shape and size. Two conditions appear to favour the production of this varicose state of the nerve-tube,—namely, a feeble power of resistance in the tubular membrane, and, secondly, perhaps, a semi-fluid state of the contained nervous pulp; and hence we find that some nerve-tubes are much more prone to become *varicose* than others. In the nerves of pure sense the tubes are very delicate in structure and very apt to exhibit this change of form, and in the brain and spinal cord they exhibit the same tendency. Ehrenberg supposed formerly that these varicosities were natural and existed during life, and that they afforded a valuable morphological character of the nerves of pure sense and the cerebro-spinal centres. But many circumstances favour the opinion that the varicosities are accidental; thus, the very irregularities above noticed in their shape, size, form, and number on a single tube are not likely to occur in the natural state. Moreover, in a piece of the brain or spinal cord not much pressed nor torn, the cylinders may be distinctly seen: even in the manipulated specimens the varicose tubes form only a small portion of the whole. And in those nerves whose fibres are not prone to become varicose, such as muscular nerves, they may be made so by firm pressure and violence in manipulation. In the nerve-tubes of young animals, in whom the tissues are more tender and contain more abundant water, these changes are also very apt to take place.

A cerebro-spinal nerve, then, consists of a congeries of fascicles or bundles of the nerve-fibres or nerve-tubes (and we shall use these terms synonymously) above described, enveloped and bound together by fibrous membrane, the nerve-sheath. The nerve-tubes lie side by side, parallel, and sometimes have a wavy course within the general sheath (*fig.* 331). The relation of the nerve-tubes to each

Fig. 331.

Diagram to illustrate the wavy course of the nerve tubes within the neurilemma.

other is simply that of juxta-position. All observers, from Fontana down to those of the present day, agree in denying the existence of any inosculation or anastomosis between the fibres in vertebrate animals; and it seems almost certain that this complete isolation of the nerve-tubes is not limited to those of the nerves, properly so called, but may be observed in the nervous centres also. When a piece of nerve is examined on a dark ground, as an opaque object, with an object glass of a quarter of an inch focus, the disposition and relation of its component tubules are more beautifully seen than by any other mode of examination. The primitive fibres present the appearance of a series of transparent tubes, containing an exquisitely delicate, soft, pearly-white material.

In point of size the nerve tubes present considerable variety even in the same trunk, while they maintain an identity of structure. The smallest tubes have very delicate walls, and are more easily rendered varicose than the larger ones. The following table gives a statement of the results of the admeasurement of the cerebro-spinal tubules in Man and other Vertebrata.

Man, and other Mammalia, from $\frac{1}{1625}$ to $\frac{1}{6500}$ of an inch.
Birds, $\frac{1}{2000}$ to $\frac{1}{3000}$ of an inch.
Reptiles, Frog, $\frac{1}{1260}$ to $\frac{1}{2280}$ of an inch.
Fish, Eel, $\frac{1}{1043}$ of an inch.
Codfish, optic nerve, $\frac{1}{650}$ of an inch.

It has already been remarked that no such thing as subdivision or branching of the primitive tubules takes place in the cerebro-spinal nerves of the vertebrate series. Whatever be the connection which each primitive tubule forms with the nervous centre, or with the textures to which it is distributed at its periphery, it passes from one point to the other without any change, save perhaps in size, and without any communication with neighbouring tubules, beyond simple juxta-position, or investment by a common sheath. This fact was recognized by Fontana, whose description of the structure of nerve, although drawn up from observations made at a great disadvantage through the imperfection of his instruments, corresponds in all essential particulars with modern observations.* And as there is the same absence of subdivision in the continuations of these nerve-tubes in the nervous centres, we may fairly infer that each point on the periphery which is in contact with a nerve-tube, is, as it were, represented by that same nerve-tube in the centre.

The structure of the cerebro-spinal nerve admits of an obvious comparison with that of the striped muscle. Both are composed of bundles of fibres, united by a sheath, which also passes between the bundles, and is a nidus for the support of the nutrient vessels. Both admit of being subdivided into primitive fibres, which are very analogous in structure. The primitive fibre of muscle (*primitive fasciculus* of some authors) consists of the true muscular tissue, or sarcous elements contained in a transparent sheath of homogeneous elastic membrane called *sarcolemma* by Mr. Bowman. The peculiar morphological characters of the primitive fibre depend upon the arrangement of the sarcous particles within this transparent tube; and to this arrangement is due any further subdivision of which the primitive muscular fibre may be susceptible. So is it with the primitive nerve-fibre: its *tubular membrane* is strictly analogous in structure and other characters with the sarcolemma. It contains the elements of the true nervous tissue or *neurine*, and this admits of a certain subdivision which may be rendered more apparent under the influence of reagents, and which is variously interpreted by different observers, and has been compared to

* Fontana sur le venin de la vipere.

the separation which takes place in the fat cells between the solid and the fluid elements of fat. As the combination of the primitive muscular fibres, in a common sheath, forms the muscle, so the union of the primitive nervous fibres, in a similar way, forms the nerve. And as the primitive fibre of muscle passes undivided from one point of the muscle to another, so the nerve tube exhibits no subdivision in its course.

Branching of nerves.—The main trunk of a nerve breaks up into its component bundles, as it passes from centre to periphery, yielding up branches to the various parts it is destined to connect with the nervous centre. These branches generally come off at acute angles, and soon plunge into the muscles and other parts to which they tend, dividing and subdividing as they proceed. Such is the most common mode of subdivision, but there are many exceptions: sometimes a branch separates from the parent trunk at an acute angle, and then turns to run in an opposite direction, forming an arch, from the convexity of which several branches are given off. Such a nerve is said to be *recurrent;* the inferior laryngeal nerve takes this course. The anastomotic arches between the emerging spinal nerves, round the vertebral laminæ, are also exceptions to the separation at acute angles.

Before a branch separates, it often happens that the parent trunk presents an enlargement for some distance above the point of visible separation. This is due to the fact that the fibres which compose the future branch begin to loosen their connection with the trunk for some way before they actually leave it; and the connecting areolar membrane becomes consequently looser and more abundant. Hence the trunk of the nerve appears enlarged, without any increase in the number of its nervous elements. This may be well seen in the auricular nerve of the neck, as it winds upwards over the sterno-mastoid muscle.

Anastomosis of nerves.—In their branchings nerves subdivide, not only to pass immediately to their muscles or other distant parts, but also to connect themselves by certain of their filaments with other nerves, and to follow the course of the latter, whether onward or retrograde, peripherad or centrad, instead of adhering completely to that of the primary trunk. By these means, nervous filaments connected with very different parts of the brain and spinal cord become bound together in the same fasciculus, and a nerve is formed compounded of tubes possessing very opposite functions. The *anastomosis* of nerves thus formed differs very obviously from the more correctly named anastomosis of bloodvessels, for in the latter case the canals of the anastomosing vessels are made to communicate and their contents are mingled; but in the former the nerve filaments are simply placed in juxta-position. There is no fusion of the one into the other, no admixture of the pulpy contents of the nerve-tubes, which continue their course as perfectly insulated as if they were placed singly and had no connexion with others.

The simplest kind of anastomosis is that which occurs in the formation of almost every spinal nerve. The anterior and the posterior roots of these nerves, emerging from different parts of the spinal cord, and possessing, as is now proved, very different functions, are united after passing through the dura mater, and bound together as one nerve; the component tubules being so completely intermixed that the future ramifications of the nerve may enjoy the double function derived from the diverse endowment of the originally component tubules.

And even in a nervous trunk thus formed there occurs a remarkable interchange of place between the component filaments, which are thereby made to decussate each other within the trunk of the nerve (*fig.* 332). Bichat says, "I amused myself one day in attentively following all the filaments of the sciatic nerve some distance

Fig. 332.

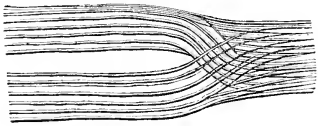


Diagram to show the decussation of the primitive fibres within the trunk of a nerve. (After Valentin.)

down the limb: those filaments which formed the exterior of the trunk above, I found, in greatest part, forming its centre below."* Kronenberg states that in some nerves these communications are so frequent that one cannot follow a single fascicle for any distance; whilst in other nerves, as the external cutaneous nerve of the arm, he found some bundles which passed through a distance of upwards of six inches without uniting with neighbouring ones. This is an anatomical fact of no mean importance, as applicable to the explanation of many apparently anomalous symptoms in neuralgic and other nervous affections.

A second form of anastomosis may be best explained by referring to that with which all who have made the superficial dissection of the neck must be familiar,—namely, the anastomosis of the descending branch of the ninth with the cervical plexus. Certain fibres, which pass from the medulla oblongata as part of the ninth nerve, leave that nerve as it crosses over the carotid artery, pass down in front of the artery, and apply themselves to a descending branch of the cervical plexus, forming in front of the carotid artery and jugular vein an arch with the concavity directed upwards, several nerves passing from the convexity to neighbouring muscles. A little careful dissection shows that some of the nervous filaments which are given off from the convexity are derived from the ninth nerve, and others from the descending branch of the cervical plexus; whilst others seem to form a complete arch and to be equally connected with both nerves. If we trace them from the ninth nerve, we find them passing upwards and backwards into the descending branch of the cervical

* Anat. Générale, t. i. p. 128, ed. 1801.

plexus, and so returning to the spinal cord. The nervous arch which is thus formed must evidently establish a communication between the cervical region of the spinal cord and that portion of the medulla oblongata whence the ninth nerve appears to arise.

We find in connexion with the optic nerve a remarkable example of this kind of anastomosis, which, as in the instance just mentioned, serves more to connect different portions of the nervous centre than to associate particular nerves. In the optic tracts of man three series of fibres may be distinguished, one which passes to the retina of the same side, another series which goes to the retina of the opposite side, decussating with the corresponding fibres from that side, and a third which passes from right to left, being apparently identified with or fused into one another at what is called the commissure, and forming a series of nervous arches, which serve to connect the opposite sides of the brain. These arches are convex towards the eyes and concave towards the brain. In the mole, in which I have failed to discover an optic nerve, this commissural band exists alone, the other two series of fibres being absent. Mr. Mayo has given a representation of these three sets of fibres belonging to the human chiasma in his admirable plates of the brain.

Volkmann gives an account of several anastomoses of this kind which he distinguishes by the expression "verschmelzungen," to which that of "fusion" appears sufficiently to correspond. The fibres of one nerve appear as if they had been fused into those of an adjacent one, and thus return to some part of the cerebro-spinal centre different from that at which it had emerged. The instances cited by Volkmann are as follows: 1. In the calf he has found an anastomosis between the fourth pair of nerves and the first branch of the fifth pair, forming an arch from the convexity of which several branches passed off in a peripheral direction. By far the greater part of these appeared, on microscopic examination, to receive their fibres from the fourth; while those fibres of the fifth which contributed to the formation of the nervous arch, passed centripetally to the brain, bound up in the sheath of the fourth nerve. 2. A similar nervous arch is found very generally among mammifera between the second or third cervical nerve and the accessory. Certain fibres, when traced from the former nerve, appeared to pass to the centre in the sheath of the latter. This anastomosis Volkmann found in the human subject, and in horses, dogs, calves, and cats.*

Another example of this kind of anastomosis has been described by Gerber, but I am not aware whether his statements have been confirmed by other observers. This consists of one or more simple loops contained in one and the same neurilemma. Certain primitive fibres emerge from and return to the nervous centre, forming a loop, with convexity directed towards the periphery, without connecting themselves with any peripheral texture or going beyond the nerve-sheath. Gerber has designated these loops *nervi nervorum*, from a supposed rather fanciful analogy to the *vasa vasorum*.

Plexuses.—The plexuses are nervous anastomoses of the most complicated and extensive kind. Those which are connected with the spinal nerves are found in the neck, the axillæ, the loins, and the sacral region, and are well described by anatomists. There are also plexuses connected with the fifth nerve, the portio dura of the seventh, the glosso-pharyngeal, and the par vagum. Each plexus is formed by the breaking up of a certain number of nervous trunks, the subdivisions of which unite together to form secondary nerves, and these again, by further interchange of fibres, give rise to nerves which emerge from the plexus, and consequently in their construction may derive their fibres from several of the trunks that enter the plexus.

The object of the various kinds of anastomosis of nerves above enumerated appears to be to associate together nervous fibres connected with different parts of the brain or spinal cord. Thus nerve-tubes of different properties or endowments become united together in one sheath, forming compound nerves; and certain sets of muscles, instead of receiving their nerves from a very limited portion of the cerebro-spinal centre, are supplied from a considerable extent of that centre, and each muscle may probably receive nerves which arise in different and distant parts of the spinal cord or brain, an arrangement whereby remote parts of those centres may be brought into connection with neighbouring muscles or other parts, or even with a single muscle.

Origin of nerves.—The connexion of a nerve with the nervous centre is called by descriptive anatomists its origin. The determination of the exact nature of this connexion is of the last importance to the adoption of a correct theory of nervous action. Yet but little is known upon this subject. The fibres of the nerves are continuous with some of those fibres of the centre, in passing into which they experience considerable diminution of size and perhaps some change of texture, (see *fig.* 330, A,) as evinced by their much greater tendency to become varicose under mechanical means than we generally find in the nerves themselves. Thus far we may confidently assert, that *every nerve at its central extremity forms a connexion with grey matter.* This fact, proved by anatomy to be constant and universal, may be considered as a law of the morphology of nerve which has the most important bearing upon its physiological action. What is the precise nature of the connexion between the two kinds of nervous matter in the centres has not yet been determined. We can see the white nerve-tubes passing between the elements of the grey matter and the vascular plexus, in the meshes of which they are deposited; but whether they form any continuity of substance with those elements, or simply come into contact with them, has yet to be demonstrated. We shall recur to this interesting and important question in the article NERVOUS CENTRES.

Termination of nerves.—Under this term

* Müller's Archiv.

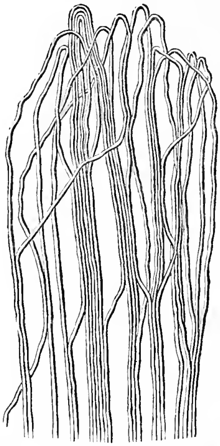
we describe the peripheral connexion of nerves with the various tissues and organs, and it is much to be regretted that our knowledge in reference to that connexion is scarcely more complete or accurate than that of their origin. The only instance in which we can speak pretty confidently respecting the peripheral connection of nerves, is with regard to muscles. In the striped muscle, nerves appear to form loops, the convexities of which are directed across the fibres of the muscles. Each nerve-fibre passes at first parallel to the direction of the muscular fibres, and then crosses them in an arched form to pass back into the bundle from which it had emerged, or to be mingled with the fibres of some neighbouring bundle, passing back in it to the centre, probably to some part of it different from the place of origin of the nerve. As far as present means of observation enable us to judge, there does not appear to be any other connexion between the nerve-tubes and the muscular fibres beyond the simple contact of the tubular membrane of the former with the sarcolemma of the latter. We have no evidence of any mingling of the true nerve-substance with the sarcous elements, and, therefore, we are forced to conclude that whatever be the nature of the influence which nerve exerts upon muscle to provoke it to contraction, that influence is exercised through the two layers of homogeneous membrane which form the investments of the nervous and sarcous elements respectively.

The best mode of observing the disposition of nerve in muscle is to examine under the microscope very thin and transparent muscles of some small animals. The abdominal muscles of the frog first afforded to Hales, and long after him to Prevost and Dumas, this opportunity; the muscles of the eyeball in small birds were used by Valentin; Burdach examined the muscles of the frog's tongue; I have found the intercostal muscles of the mouse very suitable for the purpose.

Peripheral expansion of nerves on sentient surfaces.—With regard to the disposition of nerves on sentient surfaces (the skin, for example) the most probable view appears to be that they are disposed in a plexiform manner. The nervous trunks pass toward the surface dividing and subdividing, the ramifications passing backwards to the centre in conjunction with neighbouring bundles; so that, whilst a very intricate plexus is formed, the looped arrangement, similar to that described in muscle, prevails, the convexities of the loops being directed towards the deep surface of the integuments. Gerber states, that in those parts of the skin which are provided with papillæ, the nerve-loops pass into the bases of the papillæ and form an element of their composition; and he adds, that in some instances the nerve-tube which forms the loop exhibits tortuosities or convolutions similar to those which are seen upon bloodvessels. According to the same author, in parts of the skin where the tactile sensibility is acute, the meshes of the nervous plexus are extremely small, whilst they are of large size where the skin is not highly sensitive.

The arrangement of the primitive fibres in loops has been seen by Henle on some parts of mucous membrane, in the membrana nictitans of the frog for example, and in the mucous membrane of the throat in the same animal. A similar disposition has been described and delineated by Valentin on the pulps of the teeth. (*Fig.* 333.)

Fig. 333.



Terminal nerves on the sac of the second molar tooth of the lower jaw in the sheep, showing the arrangement in loops. (From Valentin.)

Retina and optic nerve.—The examination of the peripheral connexions of the nerves of pure sense has not thrown light on the general question. The peripheral expansion of the optic nerve or the retina presents all the elements of a nervous centre; the grey matter is present in it in considerable quantity, and certain fibres continuous with the primitive nerve-tubes are likewise expanded in it. But the connexion of these fibres with the grey matter has not been detected here any more than in the centres themselves, nor has any arrangement of looping or of plexuses been demonstrated. Mr. Bowman has been led, by recent examinations, to the opinion that these fibres are the central parts of the nerve-fibre (the bands of Remak) which have been deprived of the tubular membrane and of the white substance of Schwann. It is worthy of notice that the so called optic nerve itself presents certain peculiar characters, which entitle it more to be regarded as a prolongation of the nervous centre rather than as a distinct nerve. The nerve-tubes which are met with in it are for the most part of very minute size; they admit of separation with great difficulty, owing to their not being disposed in fascicles like those of other cerebro-spinal nerves: they appear to be surrounded by and deposited in an abundant granular blastema, in which there seems to be some scattered elements of grey matter. These characters, with the peculiar construction of the peripheral expansion, would induce me to regard what is generally described as the optic *nerve* as a process of the brain itself, around the peripheral portion of which a dioptric apparatus has been disposed in order to produce those refractions in the rays of light which are necessary to the formation of an image upon the retina. And my friend, Mr. Bowman, has been led to adopt a similar conclusion from examining the structure of the retina and optic nerve.

Olfactory nerves.—The true olfactory nerves are very numerous and pass from the bulb of the olfactory process or olfactory nerve of descriptive anatomists. The peculiar characters of this process, as distinguishing it from a nerve properly so called, have long attracted attention. In truth, this process has the characters of a portion of the brain in a much more obvious way than the optic nerve, for it contains a larger portion of grey matter which adheres as a distinct layer to the white matter, as in the formation of the convolutions; and, moreover, its anterior extremity or bulb contains a ventricle which may easily be demonstrated in a recent brain. It is from this bulb that the minute threads, which may be properly called olfactory nerves, take their rise and pass down through the foramina of the cribriform plate. Nothing satisfactory is known as to the disposition of the ultimate ramification of these nerves upon the Schneiderian mucous membrane. The statement of Valentin that they form loops similar to those of cutaneous nerves is probably correct. It is not improbable that the papillæ described by Treviranus were particles of columnar epithelium to which cilia are attached.

Auditory nerve.—The auditory nerve exhibits characters sufficiently distinct from the portio dura of the seventh, beside which it lies, to have led the anatomists of former days to separate it under the name of *portio mollis*. In fact, it possesses all the appearance of cerebral substance, and it wants the fasciculated disposition which mere nerves exhibit. Its fibres are delicate and very prone to become varicose, and, as in the case of the olfactory process, it passes out of the cranium, not as a trunk, but by means of several minute filaments of various size which pierce the foramina of the cribriform floor of the internal auditory foramen. Most observers express themselves in favour of the opinion that the terminal filaments are disposed in a looped form upon the membranous labyrinth and the cochlea. Valentin describes and delineates a plexiform arrangement, with loopings of *some* of the primitive fibres; others of them, however, he says, do not affect this disposition, but appear to have free extremities. And this description corresponds with that which Henle has given. This author states that from researches which he has made upon the lamina spiralis of mammifera and the ampullæ of the frog, he has no doubt of the existence of fibres which pass from one fascicle to another in a looped form; but he finds it difficult to determine whether all the tubes contained in each fascicle form similar loops. Wagner delineates the looped arrangement, and Pappenheim adopts the same view. Mr. Wharton Jones states that the tubular structure of the nervous filaments ceases among grains of nervous matter, arranged into a sort of expansion, (see ORGAN OF HEARING), and he denies the existence of an arrangement in loops. My own observation leads me to concur in this description; and I would add that there seem to be here, as in the retina, some elements of the grey nervous matter scattered among the primitive filaments. This fact did not escape Valentin, for he remarks the existence of "very large globules" among the primitive fibres, similar to what he and Purkinje had noticed in the grey matter of the olfactory bulbs.* If this view of the peripheral expansion of the auditory nerve be correct, its analogy with the optic is very obvious; and it may be conjectured of the ear, as in reference to the eye, that around a process from the brain an apparatus has been organized fitted to transmit and modify sonorous undulations.

In the present state of observation we should not be justified in making any positive statement with reference to either the central or peripheral connexions of the nerves, beyond the following: that at the centres the grey and white elements are always associated, and that nerves may be truly said to arise out of grey matter; and that at the periphery, the nervous fibres, which in their progress from centre to circumference were bound together, become separated, and connect themselves, probably by intimate adhesion, with the elementary parts of the tissues and organs to which they are distributed.

Of the ganglionic nerves.—Without more exact information respecting the minute anatomy of these nerves, our knowledge of the peculiar function of the ganglionic system must be very incomplete. The following questions suggest themselves in reference to this system. 1. Are its anatomical characters sufficiently distinct from those of the cerebro-spinal system to warrant us in separating it from that system, if only for purposes of description? 2. Is it an independent system, as some have conjectured, giving fibres to the cerebro-spinal nerves as well as receiving some from them. 3. If it be an independent system, wherein consist the peculiar features by which its fibres are to be distinguished from those of cerebro-spinal nerves?

There are many features belonging to this system which justify its separation from that of the brain and spinal cord. The great number of ganglions connected with it, suggests the propriety of designating it *ganglionic* system, nor does the existence of ganglions on the posterior roots of spinal nerves render this appellation less proper; for in this system every nerve, nay every fibre, is connected with or passes through one or more ganglions. The external aspect of these nerves is very characteristic. Their neurilemma is very dense, and has more of the silvery appearance of white fibrous tissue than the sheaths of cerebro-spinal nerves; they want the fasciculated character of the latter nerves, and their colour has a diffused greyish or greyish red hue. The smaller ramifications are exceedingly delicate and appear to be soft,

* Valentin, über den Verlauf und die letzen Enden der Nerven, p. 63.

and therefore have been classed among the *nervi molles* by anatomists. In its peripheral distribution this nerve is prone to attach itself to the coats of bloodvessels, so much so, in fact, as to give it the character of an arterial or venous nerve; for, with a very few exceptions, it is always conveyed to organs along the bloodvessels which are distributed to them. In its distribution it is entirely or almost confined to the trunk, and probably has no connexion with the extremities; or, if it have, that connexion must be by very few fibres, and those attached exclusively to the larger trunks of bloodvessels. The peripheral ramifications of this nerve are always plexiform, and being distributed on some non-symmetrical parts, the plexuses which are derived from opposite sides of the body meet and anastomose along the mesial plane. The solar plexus, for example, derives filaments from the right and left trunks of the sympathetic, and the plexuses which accompany the superior and inferior mesenteric arteries, are also supplied from each side. Of the precise nature of these plexuses nothing is known: it is obvious, however, that their median anastomoses constitute a very peculiar feature, which strikingly distinguishes the sympathetic from the cerebro-spinal nerves, which do not anastomose along the mesial line. If in these anastomoses the looped arrangement exist, it might be conjectured to form a commissural connection between opposite and symmetrical portions of the sympathetic or of the brain or spinal cord.

To determine the independence of this portion of the nervous system on the brain and spinal cord, it would be necessary to shew either that it possessed peculiar fibres distinct in characters from the cerebro-spinal fibres, which originated in the ganglia, and were occasionally bound up with cerebro-spinal nerves, or that fibres belonging to the ganglionic nerves, although exhibiting no essential difference from the cerebro-spinal, had their origin from the ganglia and not from the brain or spinal cord. The present state of the investigations into this subject does not enable us to determine these points; but there can be no doubt that at least a large proportion of the fibres which compose the sympathetic exhibit no essential difference from those of the cerebro-spinal nerves.

When a portion of a sympathetic nerve is examined under the microscope, it is found to contain an unusually large quantity of white fibrous tissue, the fibres of which are arranged longitudinally. Crossing these are some fine circular fibres (of yellow elastic tissue) which are placed at some distance apart from each other. When the nerve is torn up by needles, numerous small oval cells may be seen among the fibres, their long axes being parallel to the fibres; these cells become much more visible when the fibrous tissue has been acted upon by acetic acid. They are scattered among the other elements of the nerve, and are probably persistent nuclei of the same kind as those which exist in muscle and other tissues. Numerous nerve-tubes are also seen entering into the formation of these nerves. These tubes appear to correspond in structure exactly with those of the cerebro-spinal system; they present the same clear outline, and contain a semifluid pulpy matter, which is acted upon in a similar way by reagents as that in the nerve-tubes of the cerebro-spinal system. They resemble, however, the nerve-tubes of the brain or spinal cord more than those of nerves, for they are much smaller and more delicate than the latter, and more prone to form varicosities. They lie side by side of each other as in other nerves, and do not inosculate. The number of these nerve-tubes seems to vary in different parts of the sympathetic, apparently without regard to the size of the nerve, so that a small nerve may contain several nerve-tubes, while a large one contains but a few. In the abdominal ramifications the nerve-tubes are very numerous, and also in the cardiac nerves, while the sympathetic trunk in the neck contains but a few, which are situated quite in the centre of the nerve.

So far all observers appear to agree in their statements respecting the elementary composition of this nerve, and so far its intimate structure justifies the opinion that in its functions it must be intimately connected with the cerebro-spinal nerves. A coarser anatomy had already taught us that this nerve has extensive communications with the cerebro-spinal system, with all the encephalic nerves, excepting those of pure sense, and with all the spinal nerves by their anterior and posterior roots. It is now evident from microscopic observation that the object of these communications must be to enable cerebro-spinal nerve-tubes to pass into the sympathetic system; and, in short, that these communications may be regarded as so many origins of the sympathetic from the brain and spinal cord.

It remains to inquire whether there is any good foundation for the doctrine that the sympathetic nerve contains distinct and peculiar fibres, (*grey fibres* of some authors,) which are independent of the brain and spinal cord, and which by anastomosing with cerebral or spinal nerves may confer upon them, to a certain extent, the peculiar endowment which is supposed to characterise the nerves of the former kind.

Retzius and Müller appear to have been the first to put forward distinctly the opinion that certain cerebro-spinal nerves received particular fibres from the sympathetic, as the latter received filaments from the former. And Müller* suggested that both the ganglionic and the cerebro-spinal nerves should be looked upon as compound in structure; "that the ganglionic nerves contain motor, sensitive, and organic fibres, of which the latter kind alone have the power of regulating the vegetative processes, and have a special relation to the ganglia; that the cerebro-spinal nerves are likewise composed of motor, sensitive, and organic fibres, of which those of each kind have their specific destination, and run their course together without uniting with the others; that the ganglionic nerve consequently differs only in having numerous ganglia, and in containing a large number of grey fibres, which give it a proportionally greyer colour; while,

* Müller's Physiology, by Baly, p. 710, 2d edit.

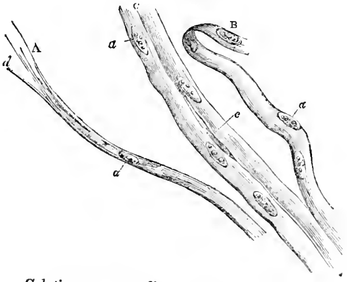
in the cerebro-spinal system, the grey fibres are less numerous, and are seen as grey fasciculi lying in the larger mass of white fibres."

Neither Retzius nor Muller has given a clear description of these organic fibres as seen by them. Muller quotes and adopts Remak's account of the microscopic examination of these fibres. "They are," according to the latter anatomist, "much more minute than the cerebro-spinal fibres; they are perfectly homogeneous, that is to say, not composed, as far as can be distinguished with the microscope, of a tube and contained portion; and are so pale and transparent that in a strong light they are not visible; lastly, a completely characteristic appearance is produced by the small roundish or oval bodies which here and there beset their surface." They are almost gelatinous in their nature; they have on their surface the appearance of fine longitudinal lines, and are easily resolved into very fine fibres.*

Schwann seems to confirm this description, and to regard the organic fibre as a less perfectly developed state of the nerve-tube of the cerebro-spinal system.

Henle in his description of the grey or soft nerves gives the following account of these fibres (*fig*.334). They are flat fibres, very clear, of homo-

Fig. 334.



Gelatinous nervous fibres from a soft nerve in the Calf (from Henle.)

B, A fibre doubled on itself, shewing the flattened character.
C, Two fibres lying in juxtaposition.
a, a, a, nuclei.
c, a nuclear fibre (*Kernfaser.*)
d, a fibrilla.

geneous appearance, in diameter from 0.002 to 0.003 of a line ($\frac{1}{6000}$th to $\frac{1}{1000}$th of an inch), with numerous nuclei of cells, round and oval, most of them laid flat, and arranged at nearly equal distances, many presenting regular nucleoli, and pointed at their opposite poles. Their longest diameter is generally parallel to the longitudinal axis of the nerve. Sometimes one of these fibres resolves itself into more delicate fibrillæ, resembling the primitive fibre of cellular tissue. Acetic acid dissolves them, and leaves the nuclei untouched. Henle admits that the greyish colour of the nerves depends on the quantity of these fibres; the greater the number of nerve-tubes, the more the bundle resembles an ordinary cerebro-spinal nerve. In the roots of the sympathetic the number of the grey fibres is in large proportion, there being four to six of them for one nerve-tube, so that each nerve-tube appears surrounded by the nucleated fibres.*

Valentin, who admits the existence of fibres of a similar kind to those described by Henle, maintains that they are continuations of the sheaths of the globules which exist in the ganglia, and which are prolonged from them into the nervous trunks, and they serve as an envelope or protecting sheath to the cerebro-spinal nerve-tubes. Henle, who had formerly regarded these fibres as nerves distributed to the contractile cellular tissue and to vessels, ("the slight developement of the nerves of these tissues seeming to correspond to the imperfection of their contractile power,") now expresses great doubts as to their nature and office, and proposes to call them *gelatinous nervous fibres;* "a name," he says, "which has no other end but to designate their presence in certain nerves, in the same way as we continue to call the fibres of cellular tissue, which are met with in tendons, tendinous fibres."

Müller conjectures that they may serve the purpose of establishing a communication between the ganglia; in short, that they are so many commissures between these centres.†

Purkinje and Rosenthal describe the organic nerve-fibre as the same as the central axis of the cerebro-spinal nerve-tube deprived of its investing membrane, and from comparing the sympathetic fibres with the cerebro-spinal fibre in the young embryo, they state their opinion that the latter, in an early stage of developement, is identical with the former, but they do not appear to recognise, as Remak did, any continuity between these organic fibres and the ganglionic globules.‡

Volkmann and Bidder have lately put forward an examination of this question; and these observers maintain the existence of a series of fibres peculiar to the sympathetic and distinct from those of the brain and spinal cord. Their work, however, contains many statements so much at variance with those of preceding writers, and with what I have myself seen, that I am led to entertain a strong suspicion that there must have been some fallacy affecting their observations throughout.

The sympathetic fibre, according to these writers, differs from the cerebro-spinal fibre in the following particulars; it exhibits at its margin a single contour, instead of the double one which is so constant a feature of the cerebro-spinal fibre, especially when examined some time after death; the distinction between a containing tube and the pulpy contents is not manifest; the fibre has sometimes a greyish aspect, which the authors regard as independent of any admixture with material foreign to that of the nerve-fibre itself; it is much smaller than the cerebro-spinal fibre, nearly one-half; in the cerebro-spinal as well as the sympathetic

nerves both kinds of fibres may be found, but in the latter these peculiar fibres are enormously predominant, so that $\frac{99}{100}$ths of their elements, or even a larger proportion, are composed of them; in passing into neighbouring trunks they run as often centrad as to the periphery. When the sympathetic fibres occur in cerebro-spinal nerves, they are collected into separate bundles. The nervous branches which go to the involuntary muscles contain almost exclusively the smaller or sympathetic fibres. Mucous membranes are almost exclusively supplied by these fibres. The viscera of the chest and abdomen receive nerves which are made up almost exclusively of sympathetic fibres.

[These statements are quite at variance with the results of my observations, as well as of those of Henle and Valentin.]

The authors remark a considerable difference as regards the relation which these peculiar fibres bear to the cerebro-spinal centres in Frogs, Mammalia, Birds, and Fishes. In frogs the fine fibres originate in greatest part from the ganglions on the posterior roots of spinal nerves and from those of the sympathetic. In Mammalia the brain and spinal cord are not the only sources of the sympathetic fibres. The ganglia also probably give off some. In birds the ganglion of the vagus is a probable source of sympathetic fibres; and in fishes the great thickness of the branches of the vagus, which are very rich in the fine fibres compared with the small size of its roots which are deficient in them, indicates that the ganglion of that nerve is a source of very numerous sympathetic fibres.

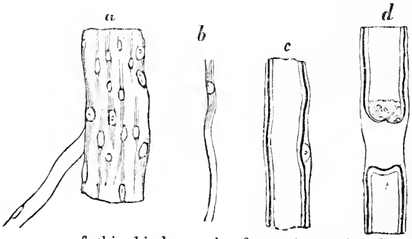
The anatomical statements of these writers would, if founded in fact, go far to confirm the opinions of those physiologists who uphold the independence of the sympathetic system, and to prove the ganglia to be distinct centres of nervous influence. It is impossible to enter further upon the discussion of this question at present, without introducing physiological arguments. In a subsequent part of the article we shall return to the subject.*

Nerves of Invertebrata.—In those Invertebrata in which a definite arrangement of the nervous system has been made out, the same elements of the nervous matter are to be found as in the Vertebrata. The grey matter consists of globules with nuclei and nucleoli precisely like those of the human brain. From the ganglia the nerves radiate; the nerve-tubes, which are very delicate and transparent in the recent state, contain a soft pulpy matter easily altered by re-agents. They are themselves collected into bundles which are surrounded by a clear transparent membrane, of the same kind as the sarcolemma of muscle, which accompanies and surrounds the branches of the nerves. As the nerve-tubes separate from the primary trunk into smaller fascicles, these sheaths bifurcate, so as to adapt themselves to the new branches. From the clear outline of the sheath, and the faintness and indistinctness of the margins of the nerve-tubes contained within it, this arrangement in the smaller nerves has very much the appearance of a bifurcation of the nerve-tubes themselves. There seems, however, no reason to believe that the nerve-tubes of Invertebrata follow a different law from that which regulates their disposition in the Vertebrate series. It is likewise highly probable that the relations of these nerve-tubes to both periphery and centre are essentially the same as in Vertebrata. Plexuses occur much more rarely, according to Valentin, in the nerves of Invertebrata.

Of the developement of nerve.—We can add nothing to the account given by Schwann of the developement of nerve. The following is quoted from Wagner's Physiology.

"The nerves appear to be formed after the same manner as the muscles, viz. by the fusion of a number of primary cells arranged in rows into a secondary cell. The primary nervous cell, however, has not yet been seen with perfect precision, by reason of the difficulty of distinguishing nervous cells whilst yet in their primary state, from the indifferent cells out of which entire organs are evolved. When first a nerve can be distinguished as such, it presents itself as a pale cord with a longitudinal fibrillation, and in this cord a multitude of nuclei are apparent. (*Fig.* 335, *a.*) It is easy to detach individual filaments from a cord

Fig. 335.



of this kind, as the figure just referred to shows, in the interior of which many nuclei are included, similar to those of the primitive muscular fasciculus, but at a greater distance from one another. The filaments are pale, granulated, and (as appears by their farther developement) hollow. At this period, as in muscle, a secondary deposit takes place upon the inner aspect of the cell-membrane of the secondary nervous cell. This secondary deposit is a fatty white-coloured substance, and it is through this that the nerve acquires its opacity (*fig.* 335, *b*). Superiorly the fibril is still pale; inferiorly, the deposition of the white substance has occurred, and its effect in rendering the fibril dark is obvious. With the advance of the secondary deposit, the fibrils become so thick, that the double outline of their parietes comes into view and they acquire a tubular appearance (*c*). On the occurrence of this secondary deposit the nuclei of the cells are generally absorbed; yet a few may still be found to remain for some time

* Die Selbstandigkeit des sympatheschen Nervensystems, &c. von. Bidder und Volkmann.

longer, when they are observed lying outwardly between the deposited substance and the cell-membrane, as in the muscles (*c*). The remaining cavity appears to be filled by a pretty consistent substance, the band of Remak, and discovered by him. In the adult a nerve, consequently, consists, 1st, of an outer pale thin cell-membrane—the membrane of the original constituent cells, which becomes visible, when the white substance is destroyed by degrees (*d*); 2d, of a white fatty substance deposited on the inner aspect of the cell-membrane, and of greater or less thickness; 3d, of a substance, which is frequently firm or consistent, included within the cells, *the band* of Remak."

From the description given in the foregoing pages, we have seen that the prevailing anatomical element of nerves is a tube composed of homogeneous membrane containing a soft pulpy matter, the true nervous substance, divisible into the white substance of Schwann and the band of Remak, and that through the medium of these nerve-tubes or fibres the grey matter of the central masses is brought into connection with the peripheral textures and organs.

Whether the fibres which Henle has designated gelatinous fibres, which resemble very much the central band of the nerve-tubes deprived of tubular membrane and white substance, perform a similar office, or whether they serve to establish a connection between the grey matter of the several nervous centres, are questions which we must leave for future consideration.

The sagacity of Galen long ago pointed out that every part, which is capable of motion, and at the same time possesses sensibility, must receive two classes of nerves, motor and sensitive. And it was reserved for the genius of Bell in our own times to demonstrate that the office of a nerve depends upon the powers or endowments of its component fibres or tubules, and that a nervous trunk may be made up of fibres of different endowments lying in juxta-position with each other.

It is at the roots of the nerves that tubules of distinct endowments are isolated from each other. Thus Bell's experiments, which have been confirmed by subsequent observations, shewed that the anterior roots of spinal nerves were motor, and the posterior sensitive; and the determination of this important fact is the foundation of all our knowledge of the physiology of nerves.

The difference in the powers or endowments of the nerve-tubes does not appear to depend upon any variety in their structure, or other physical characters, (size perhaps excepted,) for repeated examination has failed to detect any such, but rather upon their peripheral and central connexions. A sensitive nerve, while it is organized at its periphery in such a manner as to adapt it to the reception of impressions, must be connected with that part of the brain whose office it is to perceive the changes which such impressions can produce. And a motor nerve must be on the one hand connected with muscular fibres, and on the other associated with such a part of the brain or other nervous centre as is capable of exciting in it that change which when communicated to a muscle will stimulate it to contract.

The precise mechanism of those nervous acts, which I would distinguish as purely physical, by reason of their independence of the mind, is as yet unknown. It is still undetermined whether a distinct series of fibres (excitomotory) is necessary for them, or whether they may not be performed by the same fibres which are the channels of the mandates of the will, and of the impressions of those stimuli which are capable of producing sensation.

(R. B. Todd.)

NERVOUS SYSTEM, Comparative Anatomy of.*—In the following article it is intended to describe the anatomy of the nervous system in the different classes of animals as they rise upwards in the scale.

Acrita.—The class acrita consists of animals whose very characteristic is, that in them the nervous system is molecular, consisting of globules diffused through the cellular tissue of their bodies. Amongst them we distinguish, first, the *Polygastrica*, which are minute microscopic animals, furnished with numerous digestive cavities, in whom no nervous filaments have as yet been traced; still they, many of them, possess eye-specks, they show some indications of the sense of taste, and perform their various motions in the different fluids as if under the well-directed guidance of nervous power. These animals appear as a punctiform homogeneous mass, in which a nervous system does not as yet exist in a distinct form: the nervous matter may be, perhaps, every where diffused through the cellular tissue of their body. These latter remarks will equally apply to the next class—the *Porifera;* of which the *spongia officinalis* may be cited as an example. Its texture is soft and gelatinous, and is probably made up of nervous and muscular globules.

Polypifera.—No nervous filaments have been discovered, or described, in any of the various forms and sizes of polypiferous animals, excepting in the genus actinia, respecting which a doubt, almost amounting to a denial of the statement, exists. The actinia may be considered as an isolated polypus; it has no calcareous skeleton, and fixes itself to the rocks by its fleshy base. Spix, a German anatomist of high repute, gave plates of its nervous system thirty years ago, and described it as consisting of filaments with minute ganglia, surrounding the fleshy base just mentioned, from which were given off nerves to the different parts. [Professor Rymer Jones believes he has detected a delicate nervous thread, passing round the roots of the tentacles, embedded in a strong circular band of muscle, which surrounds the orifice of the stomach.] Mr. Bell, in dissecting several of these actinia, has not been able to detect any nervous filaments;

* The Editor is responsible for the passages included between brackets.

Cuvier has also been unable to make out any traces of a nervous system, and doubted the accuracy of the statement made by Spix. These animals are, however, extremely sensible to the touch, when expanded, and to the light when exposed to its influence. This would indicate some degree of nervous sensibility, but which we can conceive to be afforded by the nervous elements being distributed in their homogeneous structure in a manner similar to the preceding classes. In the next class, the *Acalepha*, which consists of gelatinous marine animals, Trembley,* Gœde,† Carus,‡ and other anatomists have failed to detect any distinct nervous filaments. Dr. Grant,§ however, describes what he considers a nervous system in the *Beroë pileus*, and describes it as "consisting of a double circular nervous filament, situated around the oral extremity of the body, which sends off minute filaments in each of the spaces between the eight longitudinal bands of ciliæ; these eight points, from which the longitudinal filaments come off, present minute ganglionic enlargements." This statement has been recently called in question, and it is probable that the nervous system in these animals is diffused throughout the gelatinous mass of which their bodies are composed. Dr. Milne Edwards describes and figures part of the nervous system in a larger species of Beroë *(Lesueura vitrea)*, as radiating from a single small ganglion which is closely connected with a coloured eye-speck, situated at the middle of the superior extremity of the body.‖

Radiata.—In the next group of animals, the Radiata, nervous filaments are for the first time discoverable; and this being the case, it is important that we should notice what form and direction they assume: it is that of a ray and a central point, or a nerve and a ganglion; of these several are developed; and as it is the very essence of a nervous system that it should consist of ganglions united and not separated, threads of communication are developed, called commissures, and a ganglionic system is formed, the inferiority of which is expressed in the Echinodermata by the perfect equality of all the ganglions: these ganglions are also situated at an equal distance from each other, and are determined in their number and origin by the general organization of the animals: thus we shall find that in the Asterias, or star-fish, with five rays, there are five ganglions (with radiating nerves) sending off commissures, which, inasmuch as they are situated on a spherical surface, unite them in the form of a ring. (See Echinodermata, *fig.* 23, *p.* 44, vol. ii.) This ring we may call the primary nervous ring; it is that form which we shall hereafter recognize as the essential base of even the most varied forms of a nervous system. It is only in the genus Asterias that a nervous system has been distinctly seen; and we are indebted to Tiedemann for the first description of it, in his Monograph of the Echinodermata.* In a small species of this genus, it consisted of a circular cord around the mouth, from which proceeded a filament along each ray, having, at its origin, a minute ganglionic enlargement; the nervous ring rested upon the extreme edge of the central aperture in the calcareous frame-work of the body, and the filaments rested on the inferior surface of the rays, concealed by and at the base of the tubular feet and suckers. Two other filaments, much shorter than those just described, according to Tiedemann,† are given off from each of these ganglionic enlargements, to be distributed to the stomach and other viscera. And Ehrenberg affirms that the red points situated at the extremity of each ray are eyes, and receive nerves connected with special ganglia. The statement, however, has not received confirmation from any subsequent observer; but Mr. E. Forbes describes a kind of protective apparatus appertaining to these points, consisting of a peculiar arrangement of the spines around them. [The existence of ganglia is questioned by many observers. Microscopic examination would decide the point.]

In the Echinus no nervous filaments have hitherto been discovered; but in the genus Holothuria, Cuvier observes, "that there appears to be a very attenuated nervous cord around the œsophagus."‡ This Delle Chiaje denies entirely.§ Dr. Grant, however, describes their nervous system to exist in the form of a collar around the anterior part of the body, giving off longitudinal filaments.‖

[It is remarkable that, although the nervous system be very obscurely developed in these animals, the action of the muscular integument is extremely powerful. The slightest irritation of the surface is sufficient to occasion forcible contraction of the integument to such a degree that the thin membranes of the cloaca become lacerated, and large portions of the intestine and other viscera are forced from the anal aperture. "So common is this occurrence," says Professor Rymer Jones, "that the older anatomists were led to suppose that, by a natural instinct, the animals, when seized, vomited their own bowels. It is, in fact, extremely difficult to obtain perfect specimens of the Holothuridæ from the constant occurrence of this accident."]

We may next ask what are the characteristics of an increase in developement of the primary nervous ring just mentioned, as the fundamental form of every nervous system. They are precisely these: either that it is in itself more highly developed, or that it is multiplied and repeated several times. This we shall find illustrated in nature; the former in the Mol-

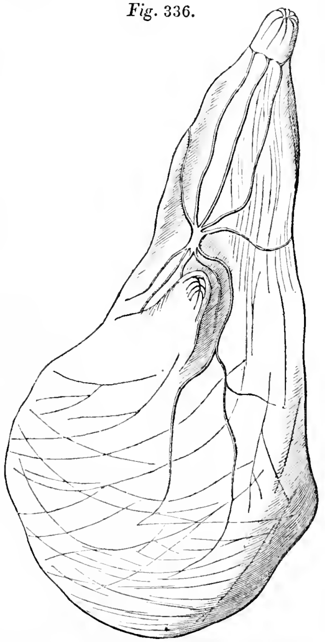
lusca, the latter in the Articulata. In the Mollusca, what is it that constitutes an increase in developement of the primary nervous ring, the characteristic form of the nervous system of that class?

1. The greater volume of a central medullary mass, and its situation on the dorsal aspect of the animal.

2. A small number of ganglions in the primary nervous ring, proportioned to the developement of the muscular system, one predominating in size over the rest, especially if that one be situated on the dorsal aspect of the animal. These ganglia are disposed unsymmetrically throughout the body, whence Professor Owen has designated these animals, in reference to their nervous system, *Heterogangliata*.

MOLLUSCA.—1. *Tunicata.*—Many of the Tunicata, the lowest of them, approach in character the Zoophytes; for no particular medullary mass constituting a nervous system is discoverable in the soft texture of their bodies, except in but few of the genera, principally in the forms of Ascidiæ. In the Ascidia mammillata (*fig.* 336), Cuvier describes and figures the nervous system* as consisting of a single oblong ganglion, situated near the anus of the animal, and between that and the branchial orifice; from this ganglion branches are given off, some of which, passing to the œsophagus, encompass it in the form of a ring.

Fig. 336.



Ascidia Mammillata, (after Cuvier,) shewing the single ganglion between the branchial and anal orifices.

* Anatomie des Mollusques.

[Mr. Garner, in his valuable paper on the nervous system of molluscous animals, describes the nervous system of *Phallusia intestinalis*. The single yellowish ganglion lies upon the muscular coat between the two orifices. One set of filaments coming from it surrounds the branchial orifice, and gives nerves to its tentacula, appearing to meet on the opposite side, forming a nerve which seems to run along the edge of the elongated branchial fold. The other set supply the muscular tunic and go towards the mouth. In *Cynthia* and those tunicata that have thick muscular tunics, the ganglion is not visible external to the muscular sac, it being situated in its interior.

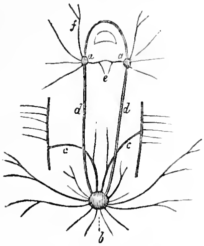
As the actions of these animals are extremely simple, so is their nervous system: by the branchial orifice water is drawn in to supply the branchiæ and to convey nutrient matters to the mouth. It is propelled by the action of numerous cilia which cover the surfaces with which it comes in contact. Through the anal orifice are expelled both the current which supplied the respiratory surface and that which passes through the digestive canal. Each orifice is provided with a sphincter muscle, which may oppose the entrance of various matters at one orifice, or resist their exit at the other. These muscles receive filaments from the ganglion. The animal is surrounded by a muscular sac, which by its contraction can compress and empty its general cavity. This, too, receives some nervous filaments. The solitary ganglion of this ascidian seems to regulate the actions of its orifices of ingestion and egestion, and of its enveloping sac on which depends the slight locomotive power of the free species. We are not prepared to deny to even this simple being that prevailing attribute of animals, a will, and therefore it may be assumed that its actions are partly volitional and partly reflex (mental and physical)—while some are, no doubt, due simply to the inherent irritability of its muscular tunic.

2. *Conchifera.*—In this order the nervous system is precisely adapted to the functions these animals have to perform. These are ingestion of the food, respiration, and locomotion. Their nervous centres or ganglia are, consequently, placed in immediate relation to the organs destined to those functions; but as one pair communicate with the others, it may be presumed to exercise an influence over them, and to be the principal centre, the analogue of the brain in the higher animals, the focus of sensation and volition.

The œsophageal or labial ganglia are for this reason the most important. They are two in number; they are situated more or less near the mouth, and are united by a transverse branch which arches over it. From these ganglia nerves are given off to the mouth, and to the tentacles, and to the anterior parts of the viscera. Each ganglion has a branch of communication to the pedal ganglion and also to the branchial ganglion.

Second in importance is the branchial ganglion. In those Conchifers in which the two branchiæ are conjoined, the ganglion continues single; where they are separate, it becomes subdivided. From this ganglion or these ganglia nerves are derived to the branchiæ and to the respiratory siphons, when present, to the posterior parts of the viscera, and to the posterior adductor muscle, also to the mantle.

Fig. 337.

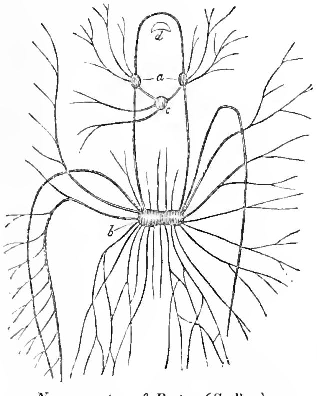


Nervous system of the Oyster, (Ostrea).
a, a, anterior ganglions. *b,* posterior ganglion. *c, c,* branches to branchia. *d, d,* connecting trunks. *e,* transverse branch uniting anterior ganglia.

In the oyster (*fig.* 337), the cockle (*Cardium*), and many others, the branchiæ are united, and there is consequently but one branchial ganglion.

In the mussel (*Mytilus*), in the scallop (*Pecten*) (*fig.* 338), &c. the branchiæ are separated and the ganglion is divided into two; their connection, however, is maintained by a commissural band. The branchial ganglia or ganglion are also united to the anterior or œsophageal ones.

Fig. 338.



Nervous system of Pecten (Scallop).
a, anterior ganglia. *b,* branchial ganglion. *c,* pedal ganglion. *d,* œsophagus.

A third ganglion, the *pedal*, is not developed in all the genera; and this circumstance, as well as its position and the distribution of its nerves, throws much light upon its function. It is immediately connected with the œsophageal ganglia by two nerves; it is always developed in the substance of the foot, generally at its base, and its size is always proportioned to the power and dimensions of that organ.

In the genus Ostracea it is entirely absent; for the foot is wanting, and whatever locomotive power is enjoyed by these animals is performed by the rapid closure of their shells through the action of the adductor muscle.

The arrangement of the nervous system in Conchifera is of the highest physiological interest. It affords a beautiful example of a complete analysis of the more complicated nervous system of the vertebrata. We have here an anterior pair of ganglia, from which filaments proceed to all parts of the body, associated too with the ingestive faculty; they are connected with whatever degree of psychical endowment the animal possesses and form its sensorium commune; they are the source of its voluntary actions. The respiratory organs likewise have their special centre in the branchial ganglion or ganglions, the development of which is always proportioned to that of the branchiæ. And there is a special centre provided for the locomotive organ, too, whose development is strictly in relation with its size and activity, and which is absent when that organ does not exist. And it must be observed that these special ganglia (respiratory and pedal), although unconnected with each other, communicate with the œsophageal ganglia.

Have we not here distinctly marked out the cerebrum (the centre of volition and sensation), the medulla oblongata (the respiratory centre), and the cerebellum (locomotive centre), as they occur in the higher vertebrata? And in the aggregate of the chords by which the œsophageal ganglia communicate with the pedal and branchial ones, do we not see the analogue of at least a portion of the spinal cord, that portion which consists of afferent and efferent nerves to and from the brain? The nervous system is distinctly adapted to the wants of the animals and their limited psychical endowment, and the same law prevails throughout the scale of animals. It is not the nervous system which developes the powers and instincts of the animal; on the contrary, these latter determine the development of the nervous system. This is well illustrated by a comparison of the oyster and the mussel. These mollusks differ only in a greater locomotive power belonging to the mussel, to effect which it possesses an organ called the foot; the oyster is devoid of such an organ. The mussel has an additional ganglion (the pedal) which the oyster has not, and this ganglion is not an isolated centre, but, like the branchial ganglion, is connected by distinct filaments with the anterior or cerebral ganglia.

A large series of careful dissections of the nervous system of these and other Invertebrata *well displayed* is a great desideratum in our public museums. We are happy to perceive that this want is likely to be supplied by the

Council of the College of Surgeons under the judicious direction of Professor Owen. The beautiful preparations of the nervous system of the mussel and other animals by our friend Mr. Goadby, cannot fail to excite the delight and admiration of every friend to the advancement of Physiology. One is not less astonished at his remarkable power of manipulation, as displayed in the dissection of the soft and fragile nerves of these delicate animals, than at the great ingenuity with which he has displayed and perpetuated these witnesses to his anatomical skill. We hope, for the sake of science, that, under the liberal patronage of the College Council, Mr. Goadby will be able to form a large collection of dissections of the Invertebrate Nervous System; and sure we are, that in nothing can the Council contribute more to promote the designs of John Hunter than in making his Museum the depository of such a series by such an artist.]

3. *Gasteropoda.*—[In this order of Mollusks the locomotive function is freely enjoyed, and is effected in many of the genera by a powerful muscular organ, which generally acts as a sucker and enables the animal to adhere forcibly to the surface and draw itself on in a crawling manner—the well known mode of progression of the common snail and slug. In other genera the foot is modified according to the objects to which the animals adhere, or locomotion is performed by portions of the mantle adapted to act as oars or fins in swimming.

The respiratory function, whether adapted to an aquatic or a terrestrial mode of existence, is much more highly developed in these animals than in the preceding order. Their digestive system, too, is more perfect, the accessory organs being more fully developed. We perceive, too, the unequivocal existence of a visual organ. There are also special organs (tentacles) for the exercise of the sense of touch, and it has been supposed that the power of smell and that of hearing existed, although the respective seats of these senses cannot be determined.

It is well known that if the surface of a snail or slug be touched ever so slightly, a contraction of the part so stimulated will immediately take place. This is probably due to the inherent irritability of the subdermic muscular layers, or it may result from the reflexion of the impression upon the motor organs from some nervous centre with which the nerves of the skin are in connexion. It seems very unlikely that we can refer it to a sensibility of the surface, for the observations of Ferussac clearly imply that the terrestrial Gasteropods present no signs of pain when injured or wounded. We cannot, therefore, agree with Professor R. Jones in assigning tactile sensibility to the general cutaneous surface of these animals, nor do we think it necessary to regard the phenomenon in question (as Dr. Carpenter suggests) as an example of motion excited by a reflected impression, which is not accompanied with sensation; but rather as an instance of muscular contraction, produced by the immediate influence of the stimulus on the irritable fibre.

Now this more active exercise of certain functions necessarily implies a greater development of the nervous system; but the same general plan as that described in the Conchifers prevails. The principal part of the nervous apparatus is connected with the œsophagus, and has communications with the other ganglia. There is also a centre of locomotion, and a respiratory centre.*

The œsophageal nervous centre is developed either as two small ganglia, situate on either side of the œsophagus, or as a single large ganglion placed on the median line and above the œsophagus; or, lastly, a single ganglion is formed beneath the œsophagus. In each of these varieties the common type of a nervous ring or collar around the œsophagus is preserved, however the situation of the cephalic centre or the number of its ganglia may differ.

The centre of locomotion consists of two ganglia, from which nerves proceed to the foot and to the mouth; which latter, however, is sometimes supplied from distinct ganglia. These ganglia are connected to each other by commissural nerves and also to the cephalic centre.

The respiratory apparatus and the viscera receive nerves from a proper centre, which sometimes is formed by one ganglion, sometimes by two separate ones, which, however, have a connexion with the cephalic ganglia. The branchial and the pedal ganglia are sometimes conjoined, and in some genera there is a still further concentration, so as to form a common centre from which nerves are distributed to all the organs.

The following examples will serve to illustrate the principal points in the nervous system of these animals:—

In *Patella* (limpet) there are two ganglia situate on either side of the œsophagus (A, *fig.* 339). From these ganglia the tentacles and

Fig. 339.

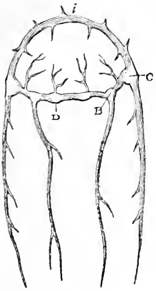
eyes are supplied with nerves, and they are connected to each other by a simple nervous band which passes above the œsophagus. From the posterior part of each ganglion two nerves pass back: the outer one terminates in the branchial ganglion, and the inner one in the pedal. The apparatus for mastication in this animal being complicated, it is supplied from a transverse band or two ganglia, situated beneath the œsophagus, and connected with the anterior or cerebral ganglia. This band is connected with two ganglia that supply the lips, called *labial*

* See article GASTEROPODA, p. 394, vol. ii., and Dr. Carpenter's Lectures on the Nervous System, Lond. Med. Gazette for 1841.

ganglia. They appear to be peculiar to Patella, but are found more distinctly developed in the Cephalopoda.

Fig. 340.



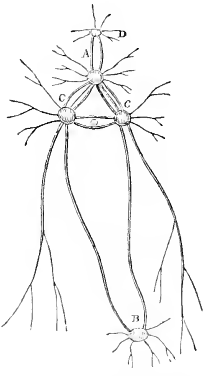
Nervous system of Chiton Marmoratus.

B, pedal ganglion.
C, branchial ganglion.
D, pharyngeal ganglion.
i, upper portion of nervous ring (cerebral ganglion.)

Fig. 340 is a representation of the nervous system of *Chiton Marmoratus* from the dissection of Mr. Garner, in which the annular form of the nervous system is very perfect. The animal presents many points of resemblance to Patella, and there is essentially the same arrangement of its nervous system. The absence of ganglia on the upper part of the ring (*i*) is attributed by Mr. Garner to the want of eyes and of tentacles.

In *Aplysia* there is an anterior or cerebral ganglion resulting from the function of two above the œsophagus (*c*, *fig*. 341), from which small nerves pass to form the pharyngeal ganglion (*p*) beneath the pharynx: from this two nerves pass backwards to form the pedal ganglion, which also gives nerves to supply the mantle (P), and in the posterior part of the body there is an additional ganglion, *the branchial* (B, *fig*. 341).

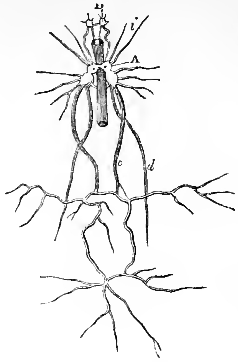
Fig. 341.



Nervous system of Aplysia.

In *Scyllæa*, according to Mr. Garner, the brain is entirely supra-œsophageal; it appears to be composed of four united ganglia, probably the cerebral and branchial. The foot has become too insignificant to require appropriate ganglia. Mr. Garner has noticed two minute black spots, one on each side of the brain, composed probably of black pigment, which he considers to be rudimentary of eyes.

Fig. 342.

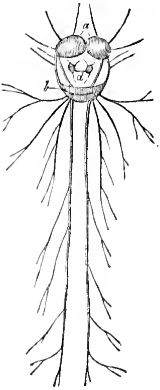


Nervous system of Scyllæa Pelagica.

A, cerebral ganglion. **D**, pharyngeal ganglion. ***c, d, i***, visceral branches.

In *Limax ater* (common slug) the nervous system is apparently much more simple; but on a little examination it will be found to consist of the same essential parts. A large supra-œsophageal ganglion, bilobed, constitutes the brain (*a*, *fig*. 343), from each side of which a pair of nerves passes downwards to join a large sub-œsophageal ganglion, which supplies nerves to the respiratory sac and to the foot or locomotive apparatus. And the pharyngeal ganglia are, as in Patella, connected with the anterior ganglion. In the sub-œsophageal ganglion we see, conjoined, the pedal and branchial ganglia.

Fig. 343.



Nervous system of the common black slug (*limax ater*).

a, supra-œsophageal ganglion. ***b***, infra-œsophageal ganglion. ***d***, anterior sub-œsophageal ganglions.

In *Buccinum undatum* the principal nervous mass is sub-œsophageal, and from it nerves pass to the branchiæ and viscera, and also to the foot and integument. The former nerves form a ganglion, which may be regarded as the branchial ganglion.]*

For the nervous systems of *Pteropoda* and *Cephalopoda*, see the articles under those titles.

Articulata.—In taking a general survey of the structure of the articulated animals, we observe that their body is divided into a certain definite number of segments, each one of which

* See Garner's paper, loc. cit.

may be considered as a repetition of the other; of these, the most anterior acquires the greatest developement, and is called the head. So in examining their nervous system, we shall find that a primary nervous ring (formed of a ganglion and two semi-circular radiating nerves) is contained in each segment. This ring, no longer closed, as in the preceding classes, but open, varies in degree of developement, according as the segment which encloses it is in a high or low degree of developement: thus, in the cephalic segment, or head, we shall always find developed a cerebral or supra-œsophageal ganglion; and, inasmuch as when a true nervous system was first formed—was first separated from the punctiform homogeneous mass of the gelatinous acrita—commissures were found uniting the primary masses of medullary substance (as we saw in the Asterias), so ought we to find, in the Articulata, commissures uniting the primary nervous rings; which latter are now become longitudinal, and the commissures of the nervous ring itself are now become radiating nerves. We ought also to find that these commissures depend, in degree of developement and in situation, on the same characters of the primary nervous ring, and consequently on the ganglia thereon developed.

We may next ask, what will mark the high or low degree of organization of a nervous system composed of several primary nervous rings? The researches of philosophical anatomy inform us, that, first, a low degree will be characterized by an *undetermined* number of those rings—by a nearly equal developement of the whole, and by the central mass of nervous matter accumulated on them being situated on the ventral surface of the animal. Secondly, a higher degree of organization exists when the primary nervous rings are repeated in a determinate manner—when some of them predominate in developement over the others, and their central medullary masses, or ganglions, are situated on the dorsal aspect of the animal. Again, as regards the uniting commissures, these will, of course, depend, in degree of developement, on the organization of the ganglions united by them; and the more perfect and the more intimate is the connexion established by these commissures, the more highly organized is the nervous system.

In the Articulata about to be described, we shall always find the most anterior nervous ring developing a ganglion on its superior surface—a true cerebral ganglion. We shall find this nervous ring repeated in the other segments of the body, but in a much more imperfect manner, for ganglions are developed only on the ventral surface of the animal; and from this latter circumstance, they, as well as their commissures, cannot be highly developed.

1. *Entozoa.*—In the lower forms of Entozoa, as in the tænia and cysticercus, no nervous system is discoverable. These animals consist of a gelatinous, more or less homogeneous mass, in which no distinct nervous system exists. In the Distoma hepaticum, the nervous system consists, according to Bojanus,* of a nervous collar or ring, with two lateral ganglions entwining the œsophagus, and two nerves which are distributed on the posterior part of the body. In the Ascaris lumbricoides, the nervous system consists of a thin double filament, without ganglia, situated in the median line of the abdomen, which separates to enclose the opening of the vulva, and to encompass the œsophagus at the lower part of the mouth. In the Strongylus gigas, according to Otto,* the median nervous filament consists of very closely approximated ganglia, thus advancing a step higher in organization, and approaching to the character of the true articulated classes.

2. *Rotifera.*—The Rotifera are minute microscopic animals: in them Ehrenberg has discovered and described a rather complex nervous organization, sufficiently so to justify their being ranked thus high in the scale of animated beings.† In the Hydatina senta, according to this anatomist, the nervous system consists of two closely approximated filaments running along the abdomen, and giving off lateral branches in their course forwards: arrived at the anterior part of the body, these nerves form a large ganglion, and then ascend to embrace the œsophagus in the form of a ring, on which minute ganglia are developed, giving off numerous filaments to the surrounding parts. There are four of these lateral ganglia, besides the large supra-œsophageal ganglion.

3. *Cirrhopoda.*—In the Cirrhopoda, the abdominal nervous cords have regular ganglia developed on them, and there is a nervous collar round the œsophagus, as in the preceding classes. Cuvier observes,‡ that in a species of Lepas he found two nervous cords situated on the ventral surface of the body, with five double ganglia developed on them, from which were given off lateral filaments to supply the curled feet. Anteriorly, and at the lower part of the mouth, these cords separated more widely, to encircle the œsophagus, above which they developed a quadrilobate ganglion, from which were given off four nerves to the viscera and muscles.

4. *Annelida.*—The nervous system of the Annelida consists of a varied number of ganglia, united by double longitudinal commissures, running along the ventral surface of the body, from which lateral filaments are given off. There is also a supra-œsophageal ganglion, which, being connected by lateral nervous cords with the first pair of infra-œsophageal ganglia, form a ring or collar, surrounding the œsophagus: this we at once recognize as the most anterior of the column of primary nervous rings, with the ganglion developed on its superior surface. I have examined the nervous system in the genera Lumbricus, Aphrodita, and Hirudo; the general plan was the same in all. In the Lumbricus terrestris, or common earth-worm, a nervous cord passed along the whole ventral surface of the animal, and presented, in a small species, the appearance

‡ Anat. des Mollusques.

of an irregular white line, the structure of which, when viewed under a lens, appeared to consist of a number of closely approximated nervous threads. In a larger species the nervous cord had a more jointed, knotted appearance, and its structure was more homogeneous; the ganglia were, however, but very imperfectly developed, for at each segment of the body of the worm, the nervous cord only offered an enlargement or swelling of rather an elongated form (*fig.* 344, *d*): the first or most anterior

a, supra-œsophageal or cerebral ganglion. *c*, infra-œsophageal ganglion. *b*, *b*, lateral nervous cords, forming the oral primary nervous ring. *d*, *d*, *d*, *d*, enlargements of the ventral cord, or imperfect ganglia, developed on the ventral surfaces of the series of primary nervous rings.

of these (the infra-œsophageal ganglion) was the largest (*c*). These enlargements were more closely approximated towards the anterior part of the body; from each of them were given off two pair of nerves, one passing to the right, the other to the left, to supply the integuments. From the more attenuated intervening portions of the cord, a single pair of filaments was given off; these filaments we at once recognize as the commissures of the nervous ring of the Radiata and Mollusca; they pass round the body and approach each other on the dorsal surface, but do not unite: in this way is an open nervous ring formed. The infra-œsophageal ganglion before mentioned diverged at its anterior part, sent upwards two lateral nervous cords (*b*), which developed a large bilobate cerebral or supra-œsophageal ganglion (*a*) of a transversely elongated oval form, thus forming a distinct nervous ring, embracing the œsophagus. From the angles formed by the divergence of the infra-œsophageal ganglia, a nerve of rather firm texture was given off; another filament had its origin from the lateral and ascending portions of the nervous collar; and from the cerebral ganglion two pairs of nerves passed forwards to supply the parts about the head. In the Aphrodita, a marine Annelide, the nervous cord had a more flattened appearance: it was about equal in width throughout its whole length, and presented similar enlargements in its course, from which nerves were given off, as in the Lumbricus; no nerve, however, arose from the intervening spaces. In the Leech, the abdominal nervous cord was surrounded by several delicate vessels, and at the anterior part of the commissures was distinctly seen to be composed of two separated columns: the ganglia were very distinct, of a round form, and twenty-four in number,—the last four or five were more closely approximated; from each were given off two diverging pair of lateral filaments, which passed to supply the muscles and viscera. The cerebral ganglion is bilobed, and sends off ten distinct optic nerves besides many smaller filaments to the integument and other parts of the head; each optic nerve terminates by expanding upon the base of a black eye-speck or ocellus.*

According to Brandt, a simple nervous filament is continued from the œsophageal ganglion along the dorsal aspect of the alimentary canal. "This," says Professor Owen, "is an interesting structure, since it offers the first trace of a distinct system of nerves, usually called the stomato-gastric in Entomology, and to which our great sympathetic and nervus vagus seem answerable."

These four classes comprise the whole of the helminthoid Articulata; and on reviewing the statements just made with regard to their nervous system, we observe that the lowest of them bear a great analogy to the Acrita and some of the Tunicata, in having no distinct nervous system discoverable; that where such does exist in the higher orders of them, it bears more or less the character before noticed as the type of the Articulata, which was, it will be recollected, a series of primary nervous rings connected by commissures; that in the Ascaris the ganglia are so imperfectly developed, and consequently their commissures, that the whole has the appearance of only a single nervous filament. As we proceed through the Rotifera and Cirrhopoda, we observe the ganglia rather more perfectly developed, but undetermined in number. In the highest of the Annelides, as the Leech, we find distinct ganglia developed and arranged in a determinate numerical series. Again, the cerebral ganglion, from being at first little more than a simple enlargement on the superior surface of the anterior primary nervous ring, has acquired, in the Leech, the form of a distinct ganglion.

We next pass to the examination of the Entomoid Articulata, in which we shall find the cerebral ganglion becoming more and more developed, and the ventral ganglia more determined as to number, and more concentrated as to situation; their longitudinal commissures have been supposed to possess two distinct nervous tracts, composed of motor and sensitive columns, giving origin to nerves having sentient and motiferous properties.

1. *Crustacea.*—In the lowest of them, the Crustacea, the nervous system presents nu-

* Owen's Lectures, p. 141.

merous forms and degrees of organization. In the common Talitrus, an inferior genus, it consists of a regular series of ganglia, developed at an equal distance from each other, united by two distinctly separated longitudinal cords, from which are given off transverse nerves. I have found the same arrangement in the genus Oniscus, in which also a close analogy to the nervous system of the Annelides was apparent. In the Cymothoa, an animal a little higher in the scale, these longitudinal columns have become closely approximated, and the ganglia have coalesced transversely. Rising higher in the scale, we find a still greater degree of concentration and coalescence in the Decapoda, this being directed to two principal points—the thorax in the long-tailed Decapods, and the thorax and abdomen in the short-tailed ones. With regard to the former, I have examined the nervous system in the genera Crangon, Processa, and Pagurus, in all of which it presented a similarity in developement. In the lengthened abdomen the longitudinal cords were very closely approximated, and the ganglia developed were nearly of an equal size, and equidistant from each other; from them were given off transverse nerves. In the thorax, the ganglia were very closely approximated indeed, longitudinally, so as nearly to have the appearance of one nervous mass, from which were given off large transverse nerves to the neighbouring parts, and from the anterior part of which there passed off two long nervous cords, which encircled the œsophagus, and developed a ganglion on its superior part. In the short-tailed Decapods, as in the common edible crab, the abdominal ganglia have coalesced into one large nervous mass, from which radiate nerves to the legs, &c.; from its anterior part there pass two long filaments, connecting it with the coalesced ganglia in the thorax. There is a supra-œsophageal ganglion, as in the preceding, but it is comparatively small.

2. *Myriapoda.*—Amongst the Myriapoda, the next class, we find the nervous system again beginning by a low state of organization, similar to the lower Crustacea, this being principally characterized by a considerable number of ganglions. In the Scolopendra morsitans, the nervous system consists of a series of twenty-one double ganglia, situated on the ventral surface of the body, connected by intervening distinctly double longitudinal cords. From each ganglion are given off lateral nerves to supply the neighbouring muscles, viscera, and feet. Those ganglia are nearly all equal in size excepting the first, which is the largest, and from which are given off additional nerves to supply the maxillæ, &c. Beyond this first sub-œsophageal ganglion, and from its anterior part, proceed the longitudinal connecting cords, which diverge to encircle the œsophagus, above which they meet and develope a bilobate supra-œsophageal ganglion. (See MYRIAPODA, *fig.* 313.) [Mr. Newport's recent researches on the nervous system of Myriapoda favour the opinion that a distinct series of excitomotory fibres connected with the ganglia of the segments (and not with the cerebral ganglion) exist in these animals. See the forthcoming volume of the Philosophical Transactions, 1843.]

3. *Arachnida.*—In the Arachnida the nervous system is more concentrated, and the ganglia are fewer; they may be considered, indeed, as intermediate in the developement of this system between the Insecta and Crustacea. In the Scorpions, according to Dr. Grant,* "the ganglia of the trunk have formed one large nervous mass, from which all the nerves of the legs and the surrounding parts take their rise as from a single ganglion." The cerebral ganglion is comparatively small, and, according to Cuvier and Carus,† the two nervous cords, proceeding thence, unite at intervals to form seven ganglions, the last of which belongs to the tail. Grant observes,‡ that the motor column is very loosely connected with the two inferior or sensitive columns, particularly in the region of the abdomen, and that this conformation is more obvious here than in any other of the Articulata. In Spiders, the nervous system consists, according to Professor Owen's description, of a brain, a bilobed ganglion which supplies the optic nerves, and also two large nerves to the mandibles. From it a short and thick collar, embracing the gullet, extends to a second very considerable stellate or radiated ganglion, situate below the stomach upon the plastron. From this ganglion five principal nerves are sent off on each side, "the first to the pediform maxillary palpi, the second to the more pediform labial palpi, which are usually longer than the rest of the legs, and used by many spiders rather as instruments of exploration than of locomotion; the three posterior nerves supply the remaining legs, which answer to the thoracic legs of Hexapod Insects. The nervous axis is prolonged beyond this great ganglion, as two distinct chords, into the beginning of the abdomen, where, in the Epira diadema, it divides into a kind of cauda equina; but in the Mygale a third ganglion of very small size is formed from which the nerves diverge to supply the teguments of the abdomen and its contents." * * * "The stomatogastric nerves are sent off from the posterior and lateral parts of the brain and form on each side a reticulate ganglion, which distributes filaments to the stomach."§

4. *Insecta.*—We have now to examine the last and highest class of articulated animals—the Insecta, in which we shall find the nervous system very highly organized, leading us by strict analogies to the Vertebrata. It consists, in almost every order, of a ganglionic nervous cord, running along the abdominal surface, as in the preceding classes, and of a similar supra-œsophageal nervous mass, called by Cuvier the brain, from which are given off eight pairs of nerves and two single ones. This nervous cord consists of a varied number of ganglia, giving off lateral nervous filaments, and connected to

* Lectures on Comparative Anatomy.

each other by sensitive columns. A tract has also been recently described by Mr. Newport,* passing along the dorsal surface of these columns, and giving off lateral nervous branches; this has been regarded as a molar tract. Minute anatomy has also unfolded to us what may be considered as the analogue of the respiratory system of nerves, and a par vagum.

These points we will now notice in detail, commencing with the Hemipterous Insecta, in which the nervous system is least perfectly organized. In the perfect state of the *Ranatra linearis* the nervous system consists (besides the supra-œsophageal nervous accumulation) of a small round ganglion (*fig.* 345, *a*), situated below the œsophagus at its very commence-

Fig. 345.

a, small round sub-œsophageal ganglion. *b*, large quadrilobate thoracic ganglion. *c*, *c*, filaments passing down the lengthened abdomen.

ment; from this two longitudinal commissures pass to join with a large quadrilobate ganglion (*b*), situated at the further extremity of the thorax. From each side of this ganglion there are given off three nervous threads, passing superiorly, transversely, and inferiorly; and from the lower part of the ganglion, which is slightly fusiform in shape, there are given off two bundles of most minute and delicate nervous filaments (*c c*), each containing five branches, which pass downwards into the lengthened abdomen to supply the parts situated in that region; there is also a supra-œsophageal nervous accumulation. In the Orthoptera the nervous system presents a certain degree of concentration worthy of notice. In the perfect state of a species of Acrydium there are two comparatively large thoracic ganglia, very near each other, and connected, as usual, by commissures; in the abdomen there are five ganglia of much smaller size, connected in a similar manner, and giving off lateral filaments: the first and second of these abdominal ganglia are some distance from each other; the three last are much more closely approximated, and are rather larger and more distinct; the cerebral ganglion is of small size.

Proceeding with the Coleoptera, we find that many of the Lamellicornes, in their perfect state, have a singular and rather unusual mode of developement of their nervous system; the ganglia are but few in number, closely approximated, and the two posterior ones give off numerous radiating filaments: this is the case with the larva of the Oryctes nasicornis, according to a dissection by Swammerdam.* In the Geotrupes stercorarius (*fig.* 346), perfect

a, bilobate thoracic ganglia. *b*, abdominal ganglia. *c*, *c*, filaments to the intestine. *d*, intestine.

state, another of the Lamellicornes, there are found in the thorax two distinctly bilobate ganglia (*a*), connected by longitudinal commissures, and one smaller ganglion at the junction of the thorax with the abdomen, immediately contiguous with which are one large and three smaller ganglia, very closely approximated to each other (*b*); the last was the longest, of rather a fusiform shape, and gave off radiating nervous filaments, particularly two long branches to the abdominal viscera and adjacent parts (*c*, *c*). The more usual form, however, of the nervous system, is such as will be described in the subsequent species.

* Philosophical Transactions for 1832 and 1834.

* Biblia Naturæ.

In the larva of Dyticus marginalis (*fig.* 347), the nervous system consists of a distinctly bilobate supra-œsophageal ganglion (*a*), from

which are given off nerves to the antennæ, and and the eyes (*b*, *c*), and of twelve abdominal ganglia, connected by longitudinal cords (*c*). The difference in distance of these ganglia is very remarkable, and worthy of mention. The first, or true infra-œsophageal ganglion (*d*) is situated as usual; between this and the second a long space intervenes, and the connecting cords are firm and distinct; the spaces between the second, third, fourth, and fifth are about equal, and not more than one-third the distance between the first described; the remaining seven are so closely approximated as to touch each other: from the terminal ganglion are given off long and minute nervous filaments, which may be traced down to the caudal extremity of the larva.

In the Hymenoptera a very great concentration and increased developement of the nervous system is met with. In the Bee the cerebral ganglion is of a large proportional size; from its anterior part are given off two nerves, which pass forward to the base of the antenna, and have their origin marked by a very distinct conical-shaped ganglionic enlargement. In the thorax all the ganglia coalesce into one central large ganglion, and a smaller one closely attached to it, giving off lateral nervous filaments; in the abdomen there are five smaller ganglia; they are connected by commissures, as in the preceding classes, the double nature of which is distinctly seen by a lens: the first abdominal ganglion is situated at some distance from the thoracic ganglion; the second and third are much nearer together, but the fourth and fifth are quite closely approximated: from them are given off radiating nerves.

The most highly developed nervous system in the Articulata occurs in the Lepidoptera, the characters of which we shall next describe. In the larva of the Saturnia pavonia minor (*fig.* 348), the nervous system consists of a bilobate supra-œsophageal or cerebral ganglion, and of twelve sub-œsophageal or abdominal ganglia (*a*), united by longitudinal fissures.

The cerebral ganglion consists of two closely approximated oblong ovate medullary masses, giving off nerves supplying the eyes and the antennæ, and a pair of nerves from its anterior and lower parts, which takes a direction forwards, and which meeting inwards and joining, forms a ganglion: from the posterior surface of this ganglion arises a nerve (the recurrent of Lyonnet) which passes backward beneath the cerebral ganglion along the œsophagus, and gives off filaments to it and the stomach.* The existence of this nerve, and particularly its situation, is of very high importance, according to the laws of philosophical anatomy: the branching filaments it sends off form nervous rings, which are important in being open below and not above, and in developing a ganglion on the dorsal aspect of the animal; this, we shall find presently, leads by strong analogies to the Vertebrata. The cerebral ganglion is supported or produced by two lateral nervous filaments, which, having their origin at its posterior part, pass downwards by the sides of the œsophagus, at the inferior part of which they converge, and are connected with the first sub-œsophageal ganglion; in this way a nervous collar or ring is formed, which encircles the œsophagus. This first inferior ganglion (*b*) is of rather a quadrilateral form; it gives off a pair of nerves to the maxillæ and to the labium (*c*, *d*), which have their origin within the termination of the lateral commissures just described. The second ganglion is longitudinally continuous with the first; from them are given off lateral nerves. The (supposed) motor and sensitive connecting nervous columns are widely separate between the second and third ganglia, and between the third and fourth; between all the others they are very closely

* This nerve is considered by Mr. Newport as the analogue of the par vagum.

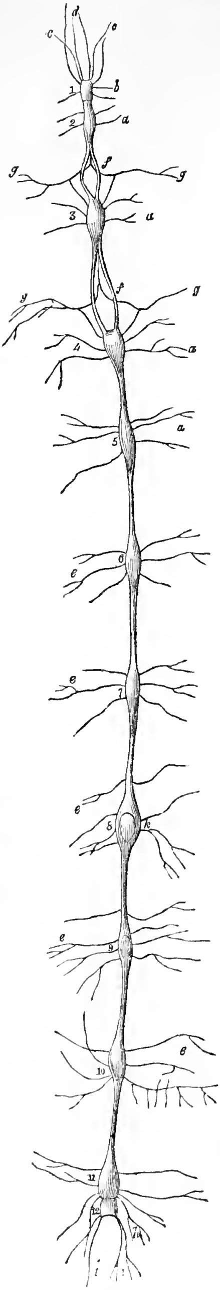

Fig. 348

approximated, though by a lens the fissure or mark of separation may in some be perceived. The abdominal ganglia are of a lengthened ovoid form; and when viewed through a lens, have a dense opaque white appearance; two in particular appear encased as it were in a neurilemma, and have a distinctly bilobate appearance; in others there appears quite a nucleus of opaque nervous matter (8 & 9); from each of them are given off three lateral pairs of nerves, some of which pass to supply the viscera, while others pass round the body of the larva to near the dorsal vessel, thus forming a nervous ring, open superiorly, which being repeated in each segment, and the whole connected by commissures, forms a continuous series at once recognised as a column of primary nervous rings, the type of the nervous system of the articulata; the eleventh and twelfth ganglia are closely joined to each other, and from the latter are given off two radiating pairs of nerves, passing to the caudal extremity of the larva. There is also a minute nerve (*fig.* 348, *f*), which I have traced in this larva passing off at the angle of separation between the divided longitudinal cords connecting the second and third, and the third and fourth abdominal ganglia, and which, midway between these ganglia, divided into a right and left transverse filament (g, g), each of which had connexion with the lateral nerves arising from the ganglia themselves. Some have considered these nerves as sympathetic, others as motor, but from their principal branches going to supply the tracheæ, I consider, with Mr. Newport, that they must be respiratory nerves.

I have examined the nervous cord in the larva of Pontia brassica, Cossus ligniperda, two species of Arctia, and have found the disposition of the ganglia, &c. to be the same; as the insect, however, advances towards maturity, considerable and important changes take place in the nervous system. Heroldt has described and figured them in the Pontia brassica,* and Mr. Newport has investigated them with the minutest accuracy in the Sphinx ligustri.† It appears that during the pupa state a contraction of the nervous columns takes place, the ganglia (more particularly the second, third, fourth, and fifth) become approximated; the distance between the cerebral ganglion and the first sub-œsophageal ganglion becomes much less, and the œsophageal ring becomes much smaller; this is preparatory to the subsequent concentration and junction which we find in the perfect insect. When this latter phenomenon takes place, the ganglia just mentioned become consolidated together, and the oral nervous ring is scarcely perceptible: this is the case in the perfect state of Mormo maura (*fig.* 349), where also the abdominal ganglia are small (*c c*), and (owing to the disappearance of two of the thoracic ganglia) are situated at some distance from these latter, which are of large size (*b b*), and the nervous

In Insects we observe a remarkable correspondence between the disposition of the nervous system and the form of the animal, and this is conspicuous not only in the adult but also in the larva state. Indeed the changes which take place in the arrangement of the nervous system as the creature passes from its immature to its mature condition, are sufficient to indicate that the same law which influences that alteration of form, promotes the adaptation of the nervous system to it; and yet, notwithstanding its apparent complication, the nervous system of insects has the same physiological signification as that of Mollusks. A cephalic ganglion, with which are united the nerves of the organs of sense, is so connected with the remaining ganglions, that its influence can extend throughout the whole system. Each segment is provided with a ganglion, which has no power beyond the limits of the segment, and which cannot act consentaneously with its fellows, except under the direction of the cephalic ganglion. The pedal ganglion of Mollusca is in insects represented by the aggregate of these ganglia of the segments, which are also doubtless the centres of the respiratory actions. And those nerves which, arising from the cephalic ganglion, are distributed to the digestive organs, the stomato-gastric nerves, are analogous to the sympathetic or to the vagus.

[It has been supposed by some anatomists that a distinct isolation of motor and sensitive function occurs in the ganglionic and non-ganglionic cords of the abdominal nervous chain of insects, as well as of other Articulata. (See *fig.* 411, art. INSECTA, vol. ii. p. 952.) But there are many objections to this hypothesis, which, indeed, must be regarded as quite untenable. It has been founded upon the anatomical fact, which is true as regards the vertebrata, that sensitive nerves have ganglions while the motor ones are devoid of them. But it is going too far to compare nerves and centres, and to argue from the nerves of vertebrata respecting the centres of Invertebrata. Moreover, as Prof. Owen remarks, the presence of ganglia on the sensitive roots of spinal nerves is not their constant character. This hypothesis also received some support from a doctrine which was countenanced by Bell, namely, that the columns of the spinal cord of vertebrata corresponded in function with that of the roots of the nerves, the anterior columns being motor as the anterior roots were, and the posterior columns and roots being sensitive. But this doctrine is utterly without foundation, as will be shewn in a subsequent part of this article. Prof. Owen adduces an important fact respecting two nearly allied Crustacea, which further invalidates the supposed difference of function of the ganglionic and non-ganglionic columns. "In the lobster (*Astacus*) and in the hermit-crab (*Pagurus*) we have two opposite conditions of a large and important part of the trunk. In the lobster the abdomen or tail is encased in a series of calcareous rings forming a hard and insensible chain armour, but as it is almost the exclusive organ by which the animal swims, it enjoys considerable motor power, a large portion of the muscular system being devoted to it. In the hermit-crab, on the other hand, the muscular system is almost abrogated in the long abdomen, for this in fact takes no share in the locomotive functions of the body: it is occupied by part of the alimentary canal and by glandular organs: the sensibility of the external integument is not impaired or destroyed by the deposition of calcareous particles in its tissue, but it retains the necessary faculty of testing the smooth and unirritating condition of the inner surface of the deserted shell which the animal chooses for its abode: minute acetabula are developed in groups upon this sensitive integument, to which also delicate ciliated processes are attached. The muscular system is reduced to a few minute fasciculi of fibres regulating the action of the small terminal claspers. Now," adds Professor Owen, "if, as has been conjectured, the ganglionic enlargements of the abdominal cords monopolize the sensorial functions, and the non-ganglionic tracts the motor powers, we ought to find the nerves, which supply the muscles of tail constructed almost exclusively for locomotion, to be derived from non-ganglionic columns; whilst in the tail, which is almost as exclusively sensitive, the ganglions ought to have been large and numerous for the supply of nerves to the integument. The contrary, however, is the fact; six well-developed ganglions distribute nerves to the muscular fibres of the lobster's tail; non-ganglionic columns supply the sensitive tail of the

* This is, however, but a rough sketch of the interesting changes that take place in the nervous system during the progress of the insect from its larva to its perfect state. Those who are interested in the matter, I beg leave to refer to Mr. Newport's highly valuable paper, where, as I have before observed, the changes of the Sphinx ligustri are detailed with minute accuracy. See also INSECTA.

hermit crab. One ganglion, indeed, is present in the Pagurus, but both its situation and office alike militate against the hypothesis of its special subserviency to sensation: it is developed upon the end of the smooth abdominal chords, and seems to have been called into existence solely to regulate the actions of the muscles of the claspers by which the hermit keeps firm hold of the columella of its borrowed dwelling."*]

On reviewing these statements of the nervous system of the entomoid Articulata, we observe that the superior ganglion of the primary nervous ring, or the cerebral ganglion, passes through several degrees of complication from the Crustacea, where it presents only slight traces of a division laterally up to the Insecta, as in the bee for instance, where it preponderates greatly in size over the ganglions, and where the sensorial nerves arising from it present distinct ganglionic enlargements. The anterior or cephalic primary nervous ring itself we see to be gradually decreasing in size from the Crustacea, where it is large and lengthened, to the highest Insecta, the Lepidoptera, where it is much smaller, and almost coalescing the superior and inferior ganglions developed on it into one ganglion. We observe that the number of primary nervous rings, with their ganglia, gradually becomes more constricted from the Crustacea through the Myriapoda (where they are developed in an undetermined length) and the Arachnida, where they are much fewer, to the Insecta, where, in their larva state, they approach the Annelides, but in their perfect state we find them developed in a regular series, and more concentrated in the regions of the head, thorax, and abdomen. These anatomical details, together with the complicated nature of the longitudinal commissures, a distinct system of nerves supposed to be for respiration, and a par vagum, demonstrate a close analogy between the ganglionic cord of the Insecta and the spinal cord of the Vertebrata, and may be considered as reasonable grounds for ranking this interesting tribe of animals the highest of the Articulata.

Further details respecting the anatomy of the nervous system of Insects will be found in the article Insecta.

Vertebrata.—We now pass to the last and highest group, the Vertebrata, where the primary nervous rings of the preceding classes have become ganglions, and their commissures have become primary nervous rings. In each segment of their bodies there is but one ganglion developed, but that one large, and situated on the dorsal aspect, and each one in the different segments is united to the other by commissures, thus forming a large median nervous mass, the primary characteristic of a true cerebral system. This will be, of course, subject to infinite modifications and degrees of organization. In the lower Vertebrata the ganglia and their commissures will be nearly equally developed; in the higher ones the ganglionic formation will predominate; and as these animals are characterized by this predominance of ganglion, its great developement takes place in that part of their body which is itself the most highly developed, the head, and the ganglionary mass itself is called the brain. On the contrary, the developement of the commissures, or of the longitudinal fibres, takes place in the opposing point to the head, viz. the trunk, and from that results what is called familiarly the spinal marrow. Again, as it is the very characteristic of the nervous matter to accumulate and develop itself on the dorsal aspect in preference, it can easily be conceived that as the ganglionic nervous matter, or brain, increases in developement, so will it influence the *direction* of the spinal marrow, and, indeed, also of the whole body. For instance, in the lower nervous formations the brain and spinal marrow are perfectly horizontal. As the former proceeds in developement, an angle, at first very acute, is formed, which gradually decreases until, in the human brain, the most perfect of all, it becomes a complete right angle. Another important point is, the *number* of ganglia and commissures that may be developed. We have already observed that each segment of the body of the Vertebrata contains a ganglion and a primary nervous ring: the number, therefore, of these latter is unfixed and variable, and depends entirely on the number of the segments of the body, or, in other words, the length of the spinal cord depends on the length of the animal. But, with regard to the masses of ganglionic nervous matter situated in that segment of the body which is the most highly developed—the head—they ought to be developed in a manner fixed and determined; and such, indeed, is the case: a division into *three* is observable in the brains of all the Vertebrata, an anterior portion or cerebrum, a posterior portion or cerebellum, a median portion, the tubercula quadrigemina. Thus the number of ganglia forming the brain, the most highly organized part of the nervous mass, is definite and invariable, while the number of ganglia forming the spinal cord, the least highly organized part of the nervous mass, is indefinite and variable. The three portions of the cerebral mass, the anterior, median, and posterior, will be designated by the names of *first*, *second*, *and third cerebral masses*; and we shall endeavour to point out the analogies which each of these portions bears in the brains of the different animals, as we ascend the scale, respecting which anatomists have various opinions.

These observations being premised, we pass to the consideration of the vertebrated classes, individually, in the manner proposed, commencing with the lowest, the fishes.

1. *Pisces.*—In these animals the nervous system presents an immense variety of forms and degrees of development. Even in the Cyclostomata, a division into brain and spinal marrow (in the general acceptation of the terms) is evident: in the former, a division into three

* Owen's Lectures, p. 171-72.

is at once seen; in the latter, the ganglia are numerous and undetermined. We will notice these parts separately.

The spinal cord* *(fig.* 351, *g*,) is remarkable for its great relative size in this class of animals: it is continued (with but very few exceptions) the whole length of the vertebral column, even into the caudal vertebræ, and it has on its anterior and posterior aspects a longitudinal fissure *(fig.* 351, *h*), the latter being the deepest; internally it is hollowed out by a canal (*i*) which traverses it in its whole extent, and which, at the upper part, immediately posterior to or underneath the cerebellum, forms a considerable dilatation or enlargement—the fourth ventricle *(fig.* 352, *e*). The posterior fissure extends to this canal. In a river lamprey *(Petromyzon fluvialis)*, weighing 570 grains, the brain weighs only four-tenths of a grain, while the spinal cord weighs three grains, the proportions being as 100 : 750. We thus observe how much the latter preponderates in size, being seven and a half times heavier than the brain. It is inclosed in a semicartilaginous case, and I satisfactorily traced it into the extreme point of the caudal extremity of the animal: it presents a thin flattened appearance, so much so that no trace of a central canal is perceptible; but immediately posterior to the brain, the rudimentary corpora restiformia of the two lateral longitudinal columns diverge to form a large excavation, which is covered over by a net-work of delicate vessels, a sort of plexus choroides; this is the fourth ventricle.

Amongst the true osseous fishes I have found a canal traversing the spinal marrow with this dilatation or ventricle at its superior portion, in the eel *(Anguilla)*, perch *(Perca fluvialis)*, gurnard *(Trigla gurnardus)*, cod *(Gadus morhua)*, mackarel *(Scomber vulgaris)*, pike *(Esox lucius)*, roach *(Leuciscus rutilus)*, dace *(Leuciscus vulgaris)*, chub *(Leuciscus ——?)*, carp *(Cyprinus carpio)*, and skate *(Raia ——?)* In the gurnard there are six pair of ganglia developed on the superior surface, immediately posterior to the cerebellum, at the origins of the nerves distributed to the large pectoral fins; this remarkable conformation only exists in this genus. In all the other species the spinal cord is of nearly equal diameter throughout, excepting towards its termination; and in the dace I traced it running to the extremity of the tail, and ending in a point: in the moon fish *(Tetrodon mola)* it is remarkably short, and terminates in a true cauda equina.

[A similar exception to the usual length of the spinal cord in fishes, is found in the *Lophius piscatorius*, in which that organ ceases as high as the eighth vertebra, and in one instance observed by Leuret as high as the second. The rest of the canal is occupied by cauda equina.]

The superior portion of the spinal cord, which takes the name of medulla oblongata, is large and broad in most fishes: on it are perceptible the corpora pyramidalia and restiformia; the olivaria are not yet developed. The former, situated on either side of the anterior longitudinal groove, are flattened and broad, and are distinctly seen continuous with the crura cerebri, the pons Varolii being wanting. The corpora restiformia, or cerebellic fasciculi, are situated posteriorly; they separate (as before observed) at their upper part to form the fourth ventricle, and pass afterwards into the cerebellum. According to Leuret there is no decussation of the fibres of the spinal cord in fishes.

[A singular little fish which has lately attracted the attention of naturalists, and for the reception of which Mr. Yarrell has instituted the genus *Amphioxus*, exhibits the apparent anomaly of an absence of all outward distinction between the brain and spinal cord. It is the *Amphioxus Lanceolatus*, of which a very perfect specimen has lately been presented to the Museum of King's College, London, by Professor Edward Forbes.

An elaborate examination of the anatomy of this little creature has been published by Mr. John Goodsir in the Transactions of the Royal Society of Edinburgh, from which we extract the following account of its neuro-skeleton and of its nervous system.

" *Neuro-skeleton.*—The osseous system, properly so called, consists of a "chorda dorsalis" tapering at both ends, without the vestige of a cranium, and of a dorsal and ventral series of cells, the germs of superior and inferior interspinous bones and fin rays. The "chorda dorsalis" consists of sixty to seventy vertebræ, the divisions between which are indicated by slight bulgings, and lines passing obliquely from above downwards on the sides of the column. In this way a separation into individual vertebræ is rather indicated than proved to exist; for although the column has certainly a tendency to divide at the points above-mentioned, yet that division is rather artificial than natural. There is no difficulty in ascertaining above sixty divisions, those at each end above the number stated run so much into one another that no correct result can be obtained.

" The chorda dorsalis is formed externally of a fibrous sheath, and internally of an immense number of laminæ, each of the size and shape of a section of the column at the place where it is situated. When any portion of the column is removed, these plates may be pushed out from the tubular sheath, like a pile of coins. They have no great adhesion to one another, are of the consistence of parchment, and appear like flattened bladders, as if formed of two tough fibrous membranes pressed together.

" As the fibres of the sheath are principally circular, provision is made for longitudinal strains on the column by the addition of a superior and inferior vertebral ligament, as strong cords stretching along its dorsal and ventral aspects. The superior ligament lies immediately under the spinal cord, and may be recognized as a very tough filament, when the column is torn asunder, or some of the vertebræ removed. The inferior ligament may be

* In the description of the spinal cord the terms anterior and posterior are used in the same signification as in the human subject; *anterior* to signify the surface next the bodies of the vertebræ, *posterior* that next the spinous processes.

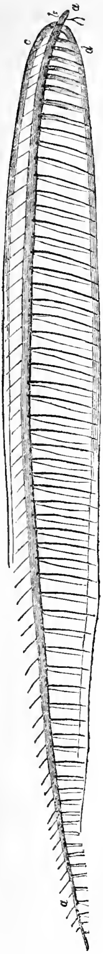

Fig. 350.

The nervous system of Amphioxus lanceolatus.

a, a, the spinal cord; *b,* the first pair of nerves; *c,* the dorsal; *d,* the ventral branch of the second pair.

raised from the inferior surface of the column in the form of a tough ribbon. From the sides of the column aponeurotic laminæ pass off to form septa of attachment between the muscular bundles; and along the mesial plane above the column, a similar lamina separates the superior bundles of each side, and by splitting below and running into the sides of the column, forms a fibrous canal for the spinal cord. Foramina exist all along the sides of this canal for the passage of the nerves. A similar septum is situated along the inferior part of the column, from the part where the inferior muscular bundles unite at the anus, to the extremity of the tail. Along the superior edge of the aponeurotic septum, between the dorsal muscular bundles, and stretching from the anterior point of the vertebral column to a point beyond the anus, and half embedded between the superior extremities of the muscles, is a series of closed cells of a flattened cylindrical form, adhering firmly to one another by their bases, so as to present the appearance of a tube flattened on the sides with septa at regular distances. Each of these cells is full of a transparent fluid, in the centre of which is an irregular mass of semi-opaque globules, apparently cells. This series of cylindrical sacs consists of the rudiments of inter-spinous bones, and probably of fin rays, and is attached below to the fibrous intermuscular septa, half covered on each side by the lateral muscles, and enclosed above by the tegumentary fold which constitutes the dorsal fin.

"A similar series of cells, with the same relations, is situated on the ventral surface of the body, and stretches from the spot where the abdominal folds terminate, to a point nearly opposite the termination of the dorsal series.

"*Nervous system.*—The spinal cord is situated on the upper surface of the chorda dorsalis, enclosed in the canal formed in the manner above described. When the whole length of this canal is displayed by removing the muscles, and then carefully opened, the spinal cord is seen lying in the interior, with nerves passing out from it on each side. It stretches along the whole length of the spine, is acuminated at both ends, and exhibits not the slightest trace of cerebral development. In its middle third, where it is most developed, it has the form of a ribbon, the thickness of which is about one-fourth or one-fifth of its breadth; and along this portion, also, it presents on its upper surface a broad, but shallow groove. The other two-thirds of the cord are not so flat, and are not grooved above, are smaller than the middle third, and taper gradually; the one towards the anterior, the other towards the posterior extremity of the vertebral column. A streak of black pigment runs along the middle of the upper surface of the cord. It is situated in the groove already described, and is in greater abundance anteriorly and posteriorly, where the nerves pass off at shorter intervals, than at the middle or broadest part of the organ. From fifty-five to sixty nerves pass off from each side of the cord; but, as the anterior and posterior vertebræ are very minute, and run into one another, and as the spinal cord itself almost disappears at the two extremities, it is impossible to ascertain the exact number, either of vertebræ or of spinal nerves. These nerves are not connected to the spinal marrow by double roots, but are inserted at once into its edges in the form of simple cords.

"The nerves pass out of the intervertebral foramina of the membranous spinal canal, divide into two sets of branches, one of which run up between the dorsal muscular bundles (dorsal branches); the other (ventral branches) run obliquely downwards and backwards on the surface of the fibrous sheath of the vertebral column; attach themselves to the antero-posterior aspect of each of the inferior muscular bundles, and may be distinctly traced beyond the extremity of each bundle. When an entire animal is examined by transmitted light, and a sufficient magnifying power, the anterior extremity of the spinal cord is observed, as before mentioned, to terminate in a minute filament above the anterior extremity of the vertebral column. The first pair of nerves is excessively minute, and passes into the membranous parts at the anterior superior angle of the mouth. The second pair is considerably larger, and, like the first pair, passes out of the canal in front of the anterior muscular bundle. The second pair immediately sends a considerable branch (corresponding to the dorsal branches of the other nerves) upwards and backwards, along the anterior edge of the first dorsal muscular bundle. This branch joins the dorsal branch of the third pair, and, passing on, joins a considerable number of these in succession, and at last becomes too minute to be traced farther. After sending off this dorsal branch, the second pair passes downwards and backwards on each side above the hyoid apparatus, and joins all the ventral branches of the other spinal nerves in succession, as its dorsal branch did along the back. This ventral branch of the second pair is very conspicuous, and may be easily traced along the line formed by the inferior extremities of the ventral divisions of the muscular bundles, the ventral branches of the other nerves joining it at acute angles between each bundle. It may be traced beyond the anus, but is lost sight of near the extremity of the tail. Twigs undoubtedly pass from the spinal and lateral nerves towards the abdominal surface of the body, but, on account of their minuteness, and the difficulty of detecting them in detached portions of the abdominal membrane, they could not be satisfactorily seen.

"When a portion of the spinal cord is examined under a sufficient magnifying power, it is seen to be composed entirely of nucleated cells, very loosely attached to one another, but enclosed in an excessively delicate covering of pia mater. The cells are not arranged in any definite direction, except in the middle third of the cord, where they assume a longitudinal linear direction, but without altering their primitive spherical form. The black pigment, formerly mentioned as existing more particularly on the upper surface and groove, is observed to be more abundant opposite the origin of the nerves; and, as it is regularly arranged in this manner in dark masses along the anterior and posterior thirds of the cord, the organ in these places, on superficial inspection, resembles much the abdominal ganglionic cord of an annulose animal. Along the middle third the pigment is not so regular, but appears in spots at short intervals. When any portion of the cord, however, is slightly compressed, and microscopically examined, it becomes evident that there is, along the groove and mesial line of its upper surface, a band, consisting of cells of a larger size than those composing the rest of the organ. Some of these cells only are filled with black pigment, but all of them contain a fluid of a brown tint, which renders the tract of large cells distinctly visible. When the compression is increased the cells burst; and the fluid which flows from the central tract is seen to contain jet-black granules, which may be detected as they escape from the cells.

"The nerves consist of primitive fibres, of a cylindrical shape, with faint longitudinal striæ. The primitive fibres of a trunk pass off into a branch, in the usual way, without dividing; and, where the trunks join the spinal cord, the primitive fibres are seen to approach close to it, but without passing into it. The greater part of the slightly protuberant origin consisting of the nucleated cells of the cord, with a few pigment cells interspersed, the exact mode of termination of the central extremities of the primitive nervous fibres could not be detected."

We hope we may be excused for quoting the following additional remarks.

"One of the most remarkable peculiarities in the Lancelet is the absence of the brain. Retzius, indeed, describes the spinal marrow as terminating considerably behind the anterior extremity of the chorda dorsalis, in a brain which exhibits scarcely any dilatation; but careful examination of the dissection of my own specimen, which I have also submitted to the inspection of Dr. John Reid, and of other competent judges, has convinced me that the spinal cord, which may be traced with the greatest ease to within 1-16th of an inch of the extremity of the chorda dorsalis, does not dilate into a brain at all. It may be urged that we ought to consider the anterior half of the middle third of the spinal marrow, where it is most developed, to be the brain, and all that portion of the chorda dorsalis which is in connection with the branchial cavity, as the cranium. That this does not express the true relation of the parts, is evident from the fact, that this portion of the cord, to its very extremity, gives off nerves, which are too numerous to be considered as cerebral, but more especially from the mode of distribution of the first and second pairs, which, in my opinion, proves the anterior pointed extremity to be the representative of the brain of the more highly developed vertebrata. A brain of such simplicity necessarily precludes, on anatomical grounds alone, the existence of organs of vision and of hearing. These special organs, developed in the vertebrata at least, in a direct relation with the cephalic integuments and the brain, could not exist, even in the form of appreciable germs, in the Lancelet. The black spot which Retzius took for the rudiment of an eye may probably have been, what also deceived me at first, a portion of the black mud which floats about in the branchial cavity, and which adheres obstinately to the parts in the neighbourhood of the oral filaments. The first pair of nerves, although very minute, in accordance with the slight development of the parts about the snout, and the want of special organs of sense, might, from their position and relations, be considered as corresponding to the trifacial in the higher vertebrata. The second pair appears to be the vagus, not only from its distribution as a longitudinal filament on each side of the body, as in other fishes, but also from its relations to the hyoid apparatus and branchial cavity, to which division of organs the eighth pair of fishes is specially devoted. The distribution of a branch of this nerve, however, along the base of the dorsal fin, and the course of the posterior part of the main branch, would appear to shew that this nerve, which I have provisionally denominated the vagus, is, in fact, the trifacial, which, in the higher fishes, is not only distributed to all the fins, but holds exactly the same relations to the dorsal and anal fins, and to the spinal nerves, as the nerve now under consideration in the Lancelet.

"The peculiarities in the structure of the spinal cord are not less remarkable than those of its configuration. It is difficult to understand, according to the received opinions on the subject, how a spinal cord destitute of primitive fibres or tubes, and composed altogether of isolated cells, arranged in a linear direction only towards the middle of the cord, can transmit influences in any given direction; and more especially how the tract of black or grey matter, if it exercises any peculiar function (excito-motory) communicates with the origin of the nerves. The nerves, also, are remarkable, originating in single roots, and containing in their composition one kind only of primitive fibres (cylindrical)."]

Brain and portion of spinal marrow of Gadus morhua (Cod-fish), about natural size.

The brain, especially in the lowest of the fishes, presents quite the appearance of a series of ganglia developed on the superior surface of the cords of the spinal marrow (*fig.* 351, *a*, *b*, *c*). In many species it is extremely small, and by no means fills the cranial cavity; in the mackarel, the volume of the brain and of the cavity destined to receive it are nearly equal. Its very small size is at once evident by comparing its weight with that of the whole body of the animal: thus in a chub, weighing 842 scruples, the brain weighed only one scruple, the proportions being as 100 : 84200; in a carp, weighing 11280 grains, the brain weighed only fourteen grains, the proportions being as 100:80600; in a roach, weighing 5030 grains, the brain weighed only nine grains and a half, the proportions being as 100 : 52,900; and, as before observed, in a lamprey weighing 570 grains, the brain weighed only four-tenths of a grain, the proportions being as 100 : 142,500. [In Leuret's table a discrepancy still more striking may be observed. This author gives as a mean the proportion 1 : 5668.*] We thus observe how small is the proportion which the size of the brain bears to that of the rest of the body, and consequently how imperfect is as yet the developement of the encephalic mass.

* Système nerveux, t. i. p. 153.

On taking a general review of the conformation of the cerebral masses forming the brain of fishes, we find it to consist of a suite of ganglia arranged behind each other—two pairs and a single one: 1st, there are two ganglia or lobes, situated the most anteriorly, *the olfactory lobes;* immediately behind which are two others, generally of larger size, *the optic lobes;* and behind these, again, is a single ganglion or lobe, situated in the median line, *the cerebellum.* On the inferior surface, immediately underneath the optic lobes, are two more ganglia. The names that have been given to these parts are extremely various; and respecting the relations and analogies which they bear to the brain of the higher animals, great difference of opinion exists.

1st. The olfactory tubercles, or *first cerebral mass* (*figs.* 351 and 352, *a*, *a*), which, with Arasky,* Serres,† Desmoulins,‡ Carus,§ and Tiedemann,‖ and contrary to Collins,¶ Monro,** Camper,†† Ebel,‡‡ Treviranus,§§ and Cuvier,‖‖ I consider as analogous to the cerebral hemispheres of man, are generally of small size, and contain no cavity (*fig.* 351, *b*). In the eel they consist of three pairs of ganglia, which increase in comparative size from before to behind; in the carp and mackarel, of only one

ganglion, situated in the median line; in the perch, gurnard, cod, pike, roach, chub, carp, and dace, of a pair of ganglia, and this is the most usual arrangement. In the skate, one of the Plagiostome fishes, where the brain is altogether more highly developed, there is one large ganglion or cerebral mass; it is solid, but in some of the sharks it contains a cavity. From these eminences, whatever be their number, the olfactory nerves (processes or lobes) arise (*figs.* 350 and 351, *k, k*), which, running together in an osseous canal for some little distance, diverge, and form large tubercles on the cribriform plate of the ethmoid bone (*fig.* 352, *l*); from these tubercles nerves arise, which are distributed to the pituitary membrane of the nose.

2dly. The optic lobes, or *second cerebral mass* (*figs.* 351 and 352, *c, b*), which Collins,* Monro,* Camper,* Ebel,* Treviranus,* and Cuvier,* considered as analogous to the cerebral hemispheres of the mammalia, but which, with Serres,† Desmoulins,† Arsaky,† Carus,† and Tiedemann,† I consider as analogous to the tubercula quadrigemina, are generally of large size in fishes, and contain internal tubercles and cavities, which communicate with the fourth ventricle. These masses may be said to arrive in this class at their maximum of developement, and we may recollect to have traced out their first rudiments in the cerebral ganglion of the Gasteropodous Mollusca, and to have noticed their successive complication of developement in the varied classes of articulated animals. In the lamprey these optic lobes are larger and more developed than any other parts of the brain; and this is what we should be led to expect from the low organization and vermiform nature of these Cyclostomous fishes: they contained in their interior a cavity. In the eel, perch, cod (*fig.* 351, *c*), gurnard, mackarel, pike, roach, chub (*fig.* 352, *b*), carp, and dace, true osseous fishes, the optic lobes are well developed, and, excepting in the eel, much larger than the olfactory tubercles before them; they are hollow, and contained tubercles, which vary in number, size, and position. In the eel there are two of these tubercles in each hollow lobe, equal in size, and situated posteriorly; in the cod there are also two, the outermost being the largest, and smooth, the inner one being smaller, and constricted in the middle (*fig.* 351, *e*); in the mackarel there are two, the anterior one being exceedingly small, the posterior much larger, slightly convoluted, somewhat resembing the Greek letter ϛ; in the pike there are two, and the floor of the cavity had a striated appearance; in the roach there is only one large tubercle; and in the carp there are two, the anterior being rather long, and passing backwards in a curved manner. From these lobes the optic nerves (*fig.* 351, *l*) arise, and cross each other, without, however, any other connexion than mere cellular tissue. The third, fourth, and sixth pairs have also their origins from these ganglia.

[The optic lobes have a direct relation in point of volume with that of the eyes, and in the pleuronecta, in which the eyes are of unequal size, Gottsche states that the optic lobes are unequal.]

The tubercles situated on the inferior surface of the brain, and immediately beneath the optic lobes just described, are generally of small size, and seldom contain a cavity; between them are the infundibulum and pituitary gland, generally of very large proportional size. Respecting their analogies and names, very much difference of opinion exists. Haller termed them the inferior protuberances of the olfactory nerves;* Cuvier considered them as the true optic lobes;† Dr. Grant calls them the cerebral hemispheres, and supposes they are the representatives of those parts in the higher animals;‡ Serres considers them appendages to the optic nerves, and analogous to the tuber cinereum;§ Vicq d'Azyr,‖ Arsaky,¶ and Carus, consider them analogous to the corpora mammillaria of higher animals:** Tiedemann†† does not decide upon this point, but judges (from the situation and form of the tubercles) that the latter hypothesis is the more probable one.

3dly. The cerebellum, or *third cerebral mass* (*fig.* 351, *f*; *fig.* 352, *c*), is but imperfectly developed in fishes; it is generally of a round form, and covers in the cavity formed by the divergence of the two cords of the spinal marrow and an enlargement of its canal, the fourth ventricle. In the lamprey there are scarcely any traces of a cerebellum, a thin transverse band of medullary matter being all that stands for it; the fourth ventricle is here, therefore, quite open and exposed. In the eel it is large, and of a rounded form; in the perch its summit is directed backwards; in the mackarel, forwards; in the cod (*fig.* 351, *f*) and pike it consists of a tongue-shaped lobe; in the gurnard, roach, chub (*fig.* 352, *c*), and dace, it is round, and of moderate size; in the carp it is also of a rounded form, but immediately behind and below it is situated another ganglion of smaller size, on each of which is a larger ganglion, principally destined for the origin of the branchial nerves, thus rendering the structure of the cerebellum very complicated, and its size very voluminous. In the Plagiostome fishes the cerebellum is much more highly developed. In the skate it is of large relative size, furnished with two lateral appendages, the commencement of lateral hemispheres, on the external surface of which transverse and longitudinal striæ were developed.

On reviewing these statements of the nervous system of the fishes, we observe two things that more particularly mark its low organization —the equality and the horizontal position of the brain and spinal marrow. In fact, as regards

the mass of nervous matter, it is greatly in favour of the spinal marrow, though, as regards complexity of structure, the brain preponderates. Again, the extreme smallness of this latter compared to the rest of the body, the simple formation of the different masses composing it, and the predominance of the median one, (which in the lower animals is the only one developed,) are points that also mark its low degree of developement. Still the groundwork of the most important structures has been laid, and we shall trace these identical parts in the succeeding classes of animals through various modifications of form and phases of developement.

2 and 3. AMPHIBIA AND REPTILIA.—We now proceed to the Amphibia, the Batrachia of Cuvier, which, in a system of arrangement, must be considered as a class distinct from the true Reptilia; but their nervous system presenting so great a similarity in structure and conformation to that class, and, indeed, differing only in an inferiority of developement, we will, to save time and space, notice the two classes of Amphibia and true Reptilia conjointly. The nervous system in these animals bears a great similarity in structure and developement to the fishes.

The spinal cord presents much the same character as in the class just described, with regard to its relative size, its extent, (excepting in the frog,) and its physical conformation. In a species of Triton weighing 39 grains, the spinal marrow weighed $\frac{1}{4}$ grain, and the brain only $\frac{1}{7}$ grain, the proportion being as 100 to 180. We thus observe that the weight of the spinal marrow preponderates over that of the brain, although not to so great an extent as in the fishes, in consequence of the increased developement of the latter. In most of the Amphibia, and in all the Reptilia, the spinal cord passes down the whole length of the caudal vertebræ, as in the fishes, but to this the frog forms an exception. In that animal it descends no lower in its adult state than barely midway between the anterior and posterior extremities, and terminates by a few nervous filaments, which pass downwards towards the sacrum; in the young and tadpole state, however, it is prolonged into the coccygeal vertebræ, and terminates in a point. The form and structure of the spinal cord, and of the medulla oblongata, differ but little from what has been described in the fishes. In the triton and frog there is a longitudinal fissure on its anterior and posterior aspects and a central canal communicating with the cavity of the fourth ventricle which is very large, covered over by a vascular plexus, is formed in the same manner, and bears great resemblance to the fourth ventricle described in the lamprey: in the lumbar region the spinal cord is thickened where the nerves of the extremities are given off; in the tadpole state, however, no such enlargement is visible. Amongst the true Reptilia, in the ringed snake (*Coluber natrix*), lizard (*Lacerta viridis*), and turtle (*Testudo mydas*, *fig.* 353), the spinal cord has an anterior and posterior longitudinal fissure, and a central canal (g) communicating with the fourth ventricle (*h*), which in the ringed snake and lizard is small, but deep; in the turtle, large, but shallow, and partly covered in by the cerebellum. According to Bojanus,* the spinal cord in the Chelonia becomes enlarged where the nerves for the anterior and posterior extremities are given off, and very thin between those enlargements. Carus† has observed the same enlargements, but in a less degree, in a young crocodile.

The brain is composed of a suite of ganglia approaching very much in form and character to the fishes, especially the Rays and Sharks. In the *triton* (Triton cristata), *frog* (Rana temporaria), *viper* (Coluber verus), *ringed snake* (Coluber natrix), *lizard* (Lacerta viridis, *fig.* 354), and *turtle* (Testudo mydas, *fig.* 353),

it fills the cranial cavity destined to receive it, though that cavity is very small when compared with the whole head; thus the size of the head is no criterion for the size of the brain. Its weight, too, when compared with the body, is another proof of its small size. In a turtle weighing upwards of 50 pounds, the brain (with the olfactory nerves, and a very small portion of the spinal marrow), weighed only 77 grains, the proportions being as 100 : 454,500; and, as before observed, in a triton weighing 39 grains, the brain weighed only $\frac{1}{7}$ grain, the proportions being as 100 : 27,300.

On taking a general review of its structure, we find, as before, three principal parts to oc-

* Anatome testudinis Europeæ.

† Op. cit. vol. i. p. 78.

cupy our attention,—the olfactory tubercles, situated most anteriorly, the optic lobes, situated posteriorly to these, and the cerebellum.

1st. The olfactory tubercles, or *first cerebral mass* (*figs*. 352, 353, *a*, *a*, *a*), now become obviously the cerebral hemispheres, are of an increased proportional size, are commencing to cover the tubercula quadrigemina, and contain a cavity which was first developed in the Plagiostome fishes; they are very various as to form. Amongst the Amphibia, in the triton they are elongated and oblong; in the frog, more oval they are united at their anterior parts by a commissure, but posteriorly they are separated. Amongst the true Reptilia, in the viper and ringed snake they are of a rounded form, and extended laterally; in the lizard and turtle they are oval (*figs*. 353, 354, *a*, *a*); in the crocodile they are more extended laterally. On cutting into them, in the turtle there is found an oblong tubercle analogous to the corpus striatum (*fig*. 353, *b**), on the inner side of which is a plexus choroides. From the anterior part of these hemispheres in the different animals mentioned, the olfactory nerves arise, and run forwards to the cribriform plate of the ethmoid bone, on the upper surface of which, in the viper and lizard, they form a bulbous enlargement (*fig*. 354, *g*): in the turtle this is wanting, but at their origin they form a large round hollow swelling, situated immediately anterior to the cerebral hemispheres, and communicating with the cavities in their interior (*fig*. 353, *i*, *k*, *l*).

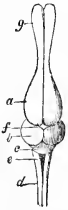

Fig. 354.

a, first cerebral mass or cerebral hemispheres. *b*, second cerebral mass or optic lobes. *c*, third cerebral mass or cerebellum. *d*, spinal cord, with its posterior longitudinal fissure. *e*, fourth ventricle. *f*, Pineal gland. *g*, olfactory nerves, with their bulbous enlargements.

2d. The optic lobes, or *second cerebral mass* (*figs*. 353, 354, *b*, *b*, *b*), are of small size, and are more solid than the same parts in the fishes, the internal cavity being smaller: we thus see them gradually approaching to the form and character of the tubercula quadrigemina of the Mammalia, and of man. In the triton, frog viper, ringed snake, lizard (*fig*. 354), and turtle (*fig*. 353); they are of a rounded form, and situated on a plane immediately posterior to the cerebral hemispheres. In all these species there is found also, immediately anterior to them, and partly covered by the cerebral hemispheres, a pair of small ganglia, analogous to the optic thalami of the human brain, on the superior surface of which was situated the pineal gland (*fig*. 354). These different eminences give origin to the fibres of the optic nerves.

3d. The *third cerebral mass*, or cerebellum (*figs*. 353, 354, *c*), presents some interesting grades of developement in these two classes of animals. In all of them it is small, in most of them extremely small, and covers in the fourth ventricle in a similar manner to what has been described in the fishes. In the triton and frog it consists of a thin transverse band of medullary matter, precisely analogous to the cerebellum of the lamprey, and, as in that animal, leaving the fourth ventricle quite open and exposed: in the viper and lizard (*fig*. 353) it presents a similar appearance, but the band of medullary matter is rather thicker; in the turtle (*fig*. 352) it consists of a tongue-shaped lobe, very similar to the cerebellum of the cod: there are very distinct lateral appendages, the rudiments of which we first observed in the Plagiostome fishes, and which we shall trace in the succeeding classes to increased degrees of developement: these lateral appendages are found also in the crocodile; they lead us, by strict analogies, to the cerebellum of the birds.

On reviewing these statements of the nervous system of the Reptilia, we observe that the equality and horizontality of the brain and spinal marrow again claim our attention as marks of low organization. Still, however, the preponderance of the spinal marrow over the brain is less, while the weight of this latter, compared with the body, is greater. The first cerebral mass has increased in size; cavities are developed in its interior, and it is united into two portions, which are divided by a commissure. The second cerebral mass, or tubercula quadrigemina, has decreased in size, and the cavities are much smaller. The third cerebral mass, or cerebellum, is in the lower Reptilia imperfectly developed, but in the higher ones it is of some size, and marked by external striæ.

4. Aves.—In the class Aves, or birds, the nervous centre has acquired a high degree of developement in all its parts, but particularly as regards the cerebellum, and the different portions composing the cerebral mass are arranged more above and less behind each other. The spinal cord (*fig*. 355, *d*) is of less relative size, and of less extent, than in the fishes and reptiles, but it still is traversed by an anterior and posterior longitudinal fissure, and still contains a central canal. In a pigeon weighing (according to Carus) eight ounces, (360 grains) the brain weighed 37 grains, and the spinal marrow only 11 grains, the proportion being as 100 : 30. We thus observe that the brain now preponderates in size over the spinal cord for the first time; this at once marks its increased developement. Where the nerves supplying the anterior and posterior extremities are given off, the spinal cord presents distinct enlargements, the inferior of which is the largest, and is placed in the sacrum: this may be considered as the termination of the spinal cord, for Carus considers that portion passing through the coccygeal vertebra to be only a large terminal filament. A canal passes through the whole extent of the spinal cord, which, at the inferior enlargement, forms a large and remarkable excavation, called the

rhomboidal sinus: this may be seen in the goose. The medulla oblongata, with the pyramidal and cerebellic fasciculi, present similar characters to the same parts in the fishes; the corpora olivaria, and pons Varolii, are not yet developed.

The brain of birds is composed of a similar number of parts as in the reptiles, but they are more highly developed, and they are no longer arranged in a longitudinal series as formerly, but more on the top of each other. In the sea-gull (*Larus cyanorhynchus*, *fig.* 355), snipe (*Scolopax gallinula*), red start (*Motacilla* —— ?), goldfinch (*Fringilla carduelis*), fowl (*Phasianus gallus*, *fig.* 356), pigeon (*Columba* —— ?), and hawk (*Falco nisus*), the brain fills entirely the cranial cavity, this cavity now corresponding exactly with the size and form of the head. It is of increased relative size compared with the body: in a pigeon, weighing according to Carus 3360 grains, the brain weighed 37 grains; the proportions being as 100 : 9,100.

On taking a review of its structure, we find three principal portions, as heretofore, to occupy our attention, the conformation of each being very uniform in the whole class: 1st, the cerebral hemispheres; 2d, the optic lobes; 3d, the cerebellum.

1st. The cerebral hemispheres, or *first cerebral mass*, are large (*figs.* 355, 356, *a*, *a*), of greater relative size than any other parts of the brain, and vary but little in form; in the embryo

Fig. 355.

a, a, first cerebral mass or cerebral hemispheres. *b, b,* second cerebral mass or optic lobes. *c,* third cerebral mass or cerebellum, with its transverse grooves. *d,* spinal cord, with its posterior longitudinal fissure.

chick on the sixteenth day, however, I found them very little larger than the optic lobes (*fig.* 357, *a*). In the sea-gull and snipe they are of an oblong form, and larger posteriorly; in the hawk more round and short; in the red-start, goldfinch, pigeon, and embryo chick, on the twentieth day, more lengthened in form and covering quite the optic lobes (*fig.* 357, *a*). In the ostrich they are also lengthened and approach very much the form and characters of the same parts in the lower Mammalia. These hemispheres are united to each other by a commissure (the anterior commissure); above

a, a, first cerebral mass or cerebral hemispheres, oval in form. *b, b,* second cerebral mass or optic lobes, widely separated from each other. *c,* third cerebral mass or cerebellum, greatly increased in developement and pushing asunder the optic lobes. *d,* spinal cord, with its posterior longitudinal fissure. *g,* olfactory nerves.

this there is another one, which Meckel considers as the first rudiment of the corpus callosum;* they contain cavities which are true lateral ventricles, and in which is a tubercle or enlargement corresponding to the corpus striatum of the Mammalia. From the anterior part of this primary cerebral mass the olfactory nerves arise (*figs.* 356, 357, *g*, *g*), and pass forwards to the cribriform plate of the ethmoid bone; their origin is marked by two distinct enlargements, which are hollow and communicate with the lateral ventricle.

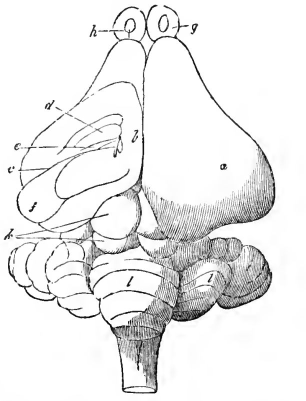
2d. The optic lobes, or *second cerebral mass*, (*fig.* 355, *b*), are of small size, and are more widely separated from each other than in the preceding classes, though they still are connected by a medullary membrane corresponding to the roof of the aqueduct of Sylvius. In the embryo of the chick on the sixteenth day, however, these parts, as before observed, are nearly as large as the cerebral hemispheres, their inner borders touching each other, as in the reptiles and fishes (*fig.* 357, *b*): at the twentieth day they are widely separated (*fig.* 356 *b*). In the sea-gull (*fig.* 355), snipe, hawk, redstart, goldfinch, fowl, and pigeon, they are of a rounded form, and situated immediately beneath the cerebral hemispheres. On cutting into them in the sea-gull and pigeon, they are found to contain a cavity, which, in the former, is very small, in the latter larger, and containing a solitary dark-coloured tubercle: their cavities communicate with the third ventricle. Between these optic lobes, and immediately inferior to the cerebral hemispheres, in the pigeon, there is situated a pair of ganglia, of a flattened form (the existence of which has been before noticed in the

* Archiv. für Physiologie.

preceding classes) analogous to the optic thalami of the brain of man: between them is the canal leading to the infundibulum.

3d. The cerebellum, or *third cerebral mass*, (*fig.* 355, *c*), is particularly well developed, exhibiting an amazingly increased degree of organization when compared with the preceding classes, and bearing great analogy to the cerebellum of the higher animals. In the before-mentioned species it consists of a more or less rounded median lobe, with very small lateral appendages; its external surface is marked by transverse sulci, varying in number, that extend a short distance into the interior of its substance. On cutting into it in the seagull, fowl, and pigeon, the appearance of the arbor vitæ is slightly perceptible. In the embryo of the chick on the sixteenth day, however, the cerebellum is very small, not yet sufficiently developed to separate the optic lobes; very slight traces only of grooves were apparent on its surface (*fig.* 356, *c*). On the twentieth day it presents all the characters of the full-grown bird, both as regards relative size, position, and external striæ (*fig.* 357, *c*).

Fig. 358.



Brain and portion of spinal cord of Lepus cuniculus (rabbit), natural size, left hemisphere sliced.

a, first cerebral mass or cerebral hemispheres, slightly grooved on the external surface. *b*, corpus callosum, short. *c*, cavity of lateral ventricle. *d*, portion of corpus striatum. *e*, tænia semicircularis. *f*, hippocampus major, the superior surface sliced. *g*, masses or ganglia of the olfactory nerves, with their cavities. *h*, bristle passed, shewing the communication between the cavity of the olfactory nerve and the lateral ventricle. *k*, second cerebral mass or tubercula quadrigemina,—the anterior pair the largest. *l*, *l*, third cerebral mass or cerebellum, very much grooved. *d**, spinal cord, with its posterior longitudinal fissure.

On reviewing these statements of the nervous system in the birds, we observe that the brain and spinal marrow are no longer situated on the same horizontal plane, and that the preponderance is now in favour of the brain: its weight, too, when compared with the body, is greater; and the ganglia composing it are more above, and less behind each other. The primary cerebral mass has now acquired so high a degree of developement as to surpass the others in size; no convolutions are, however, yet apparent on its surface; no large commissure yet exists to unite them. The optic lobes, or median cerebral mass, are small, separated from each other, and their cavities have decreased. The cerebellum, or third cerebral mass, is large; traces of lateral lobes are evident, and external striæ are perceptible.

MAMMALIA.—In the last and highest class, the Mammalia, will be found some most interesting grades of developement and structural forms of the cerebral mass to arrest our attention, and we shall observe how rapidly the different parts are added, and those already formed are more highly developed, to constitute the complex brain of the human species. The spinal cord (*figs.* 358, 321, 322, 323, *d**) is of still less relative size than in the preceding classes; it has an anterior and posterior longitudinal fissure. In a full-grown mouse, weighing 227 grains, the spinal marrow weighed one grain and a half, the brain six grains and a half—the proportions being as 100:22. We thus observe that the former is of much less relative size than the latter.

The following is a table shewing the relative proportions of the brain and spinal marrow in the four classes of Vertebrata:—

			Brain.		Spinal Marrow.
PISCES	Lamprey....	as	100	:	750
REPTILIA ..	Triton	as	100	:	180
AVES......	Pigeon	as	100	:	30
MAMMALIA	Mouse	as	100	:	22

The spinal cord passes lower down the vertebral column than in man, but terminates by a true cauda equina, as in the bat and mouse, in which latter animal it is continued into the sacrum, but not into the caudal vertebræ, as in the preceding classes. In the bat the spinal cord descends no lower than the eleventh dorsal vertebra, a conformation rather unusual:* the fissure on its posterior surface was deep in those animals, but it becomes less evident as we approach the human species. It presents three distinct enlargements in its course: a superior one, the medulla oblongata; a median, and a posterior one, where the nerves for the extremities are given off: this is the case in the mouse and bat, though in the former animal the superior and median enlargements are so closely approximated as to render the spinal cord of great thickness in the thoracic region of the body.†

The following is a table shewing the relative proportions of the body and brain in the four classes of Vertebrata:—

* Meckel (Archiv. für Physiologie) also states, that in the hedgehog the spinal cord terminated in the thoracic vertebræ.

† Carus remarks the same thing in many of the Mammalia with a short neck; the Rodentia, for instance.

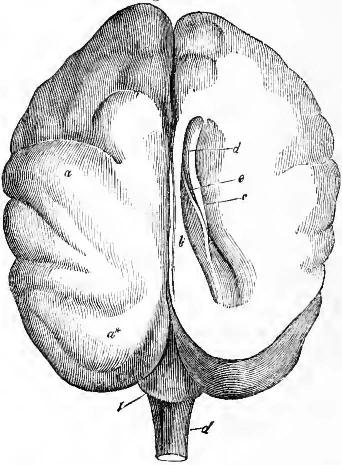
		Brain.	Body.
PISCES	Carp......	as 100 :	80,600
	Chub.....	as 100 :	84,200
	Roach.....	as 100 :	52,900
	Lamprey...	as 100 :	142,500
REPTILIA	Triton.....	as 100 :	27,300
	Turtle.....	as 100 :	454,500
AVES	Pigeon....	as 100 :	9,100
MAMMALIA	Sheep.....	as 100 :	22,600
	Pig.......	as 100 :	32,300
	Mouse.....	as 100 :	3,500

In the brain of the Mammalia we shall find the same parts as heretofore to occupy our attention, though at an extraordinarily increased degree of developement: this, however, varying greatly in the different orders. Its direction, with regard to the spinal marrow, is no longer horizontal, as we found in the fishes and reptiles, but approaching more or less to a right angle; the first traces of which inflection were perceptible in the birds. In the bat (*Vespertilio murinus*); mouse (*Mus musculus*); rat (*Mus rattus*); rabbit (*Lepus cuniculus*, *fig.* 358); pig (*Sus scrofa domestica*); horse (*Equus caballus*); ass (*Equus asinus*); sheep (*Ovis ammon*); deer (*Cervus dama*); mole (*Talpa Europæa*); stoat (*Mustela euninea*); cat (*Felis catus*); and monkey (*Callithrix* —— ? *fig.* 359); the brain exactly fills the cranial cavity, that cavity corresponding with the shape and size of the head. The size and bulk of the brain are greater than in any of the preceding classes, as shown by its relative weight compared with the body. In a sheep weighing, as near as could be calculated, 7466 drachms, the brain weighed 33 drachms; the proportion of the brain to the body being as 100:22600. In a pig weighing about 7116 drachms, the brain weighed 22 drachms; the proportion being as 100:32350. The brain of a horse weighed 156 drachms. In a mouse weighing 327 grains, the brain weighed 6½ grains, the proportions being as 100:3,500.

On taking a review of the structure of the brain in Mammalia, we find that it presents a great variety of form and developement in its different parts. 1. The cerebral hemispheres, or first cerebral mass, which vary greatly in their size and extent, and are united in the median line by a commissure, the corpus callosum. 2. The optic lobes, or second cerebral mass, which are here small and divided into two pairs, presenting more particularly the characters of the tubercula quadrigemina in the human brain, under which name they will in future be noticed. 3. The cerebellum, or third cerebral mass, which is greatly increased in developement, and presents a division into median and lateral portions.

1st. The cerebral hemispheres, or *first cerebral mass* (*figs.* 357, 353, *a*) are of large size, but this varies according to the order in which they are examined. In the lower ones they resemble very much the same parts in birds, with regard to their small size and their want of convolutions. In the dolphin they are very short and broad; in the ornithorynchus they are oval, and narrowed anteriorly. In both these animals their surfaces are smooth and unconvoluted. The same occurs in the opossum and myrmecophaga didactyla, amongst the Marsupialia. In the bat they are no longer than wide (2½ lines each way), leaving the tubercula quadrigemina quite exposed; they are of a triangular form, and perfectly smooth on their surface. In the rabbit (*fig.* 358, *a*), rat, and mouse, rodent animals, they are oblong ovate, but much narrowed anteriorly. The tubercula quadrigemina are quite exposed, but scarcely so much so as in the bat; their surfaces are smooth and unconvoluted, though in the rabbit there are a few slight furrows; on their inferior surface there is a faint groove, dividing them into lobes, the rudiments of the fissura Sylvii. In the pig, horse, ass, sheep, and deer, the hemispheres are more oval in form, more convex, and less narrowed anteriorly; they extend backwards, so as quite to cover the tubercula quadrigemina, and their surfaces are marked with numerous convolutions; the fissures of Sylvius are more strongly marked, and the division into lobes is more apparent. In the stoat and cat they are similarly shaped and convoluted on their surface, and they extend backwards, covering the tubercula quadrigemina and a portion of the cerebellum. In the monkey (*fig.* 359, *a*) they are more

Fig. 359.



Brain of Callithrix ——— ? (*Monkey*), *natural size, right lateral ventricle exposed.*

a, First cerebral mass or cerebral hemisphere, elevated and broad, and extending backwards, covering the cerebellum. *a**, posterior lobe of cerebrum, free from convolutions. *b*, corpus callosum. *c*, cavity of lateral ventricle. *d*, portion of corpus striatum. *e*, tænia semicircularis. *l*, third cerebral mass or cerebellum. *d**, spinal cord.

rounded, very much elevated, broader in the middle, and extend backwards, covering the cerebellum. The convolutions are more numerous than in the preceding classes; the fissure of Sylvius is a deep groove, marking the division into anterior and median lobes, and here, for the first time, are observed the posterior lobes *(a*)*, as yet but of small size, narrowed posteriorly, and free from convolutions. In the orang-outang they are altogether larger, and more approaching the form and character of the human brain, covering the cerebellum entirely, and convoluted on their posterior lobes.*

These cerebral hemispheres are united by an important commissure, which makes its first appearance in mammiferious animals, *the corpus callosum*; in the lower orders, as in the bat, rabbit (*fig.* 358, *b*), rat, and mouse, it is very short,—shorter even than the tubercula quadrigemina; in the pig, ass, and sheep, it is longer and broader; in the stoat, cat, and monkey (*fig.* 359, *b*) it is increased in length and width, approaching the characters of the corpus callosum in the human adult brain.

On cutting into the cerebral hemispheres, cavities are found in their interior, the lateral ventricles. In the bat and rodent animals, as in the rabbit (*fig.* 358, *c*), they are of small size, but large in proportion to the hemispheres; in the pig, sheep, stoat, and cat they are larger and broader, but smaller in proportion to the hemispheres. In all these animals the anterior and descending cornua are observable; the posterior are found only in the monkey (*fig.* 359, *c*), where the lateral ventricles quite approach the characters of the same parts in the human adult brain. In the interior of these ventricles are to be observed the corpora striata, tænia (for the first time observable), optic thalami, and fornix. In the bat genus and Rodentia, the corpora striata are very large, forming, indeed, the greater parts of the hemispheres of the brain, and the tænia very narrow (*fig.* 358, *d*, *e*); in the pig, sheep, and cat they are oblong and smooth; in the monkey they were also oblong (*fig.* 359 *d*, *e*), and though in reality large, appear smaller, when compared with the hemispheres, than in the preceding classes,—which apparent defects of relation Tiedemann considers evidently to depend on the greater augmentation of the hemispheres. The fornix, with its appendages, is for the first time observable in this class of animals, and exists in the brains of all the animals before mentioned; in the lower orders, its relative size, particularly of the hippocampus major, is somewhat considerable.

From the anterior part of these cerebral hemispheres the olfactory nerves arise, which still possess many points of extreme interest. In the dolphin and other Cetacea, they are entirely wanting. In all the mammiferous animals before enumerated, except the Quadrumana, they consist of oblong or rounded medullary masses, situated on the cribriform plate of the ethmoid bone, from which filaments are given off to be distributed on the pituitary membrane. In the lower orders, as in the bat, rabbit, rat, and mouse, these masses or ganglia of the olfactory nerves are situated on a plane directly anterior to the cerebral hemispheres, and may be seen on looking upon the superior face of the brain, these latter not being yet sufficiently developed anteriorly to cover them; in the pig they are nearly covered by the hemispheres; in the horse, ass, sheep, and deer, they are quite covered by them, and are only to be seen on the inferior surface of the brain; in the cat they are similarly situated, but the anterior edge of the hemispheres projects still further beyond them. In all these animals a medullary band or tract (*h*) connects them with the median lobes of the hemispheres, and in all they contain cavities (*i*), which communicate with the lateral ventricles. In the monkey the olfactory nerves (processes) consist of free, flattened, medullary bands situated on the inferior surface of the anterior lobes of the brain, precisely the same as in the human adult brain.

2dly. The optic lobes, or *second cerebral mass*, or, as they are now to be called, the tubercula quadrigemina, consist of an anterior and posterior pair of ganglia, in which cavities are no longer perceptible. They differ in size, relatively to each other as well as to the cerebral hemispheres, and in position. In the bat, rabbit (*fig.* 358, *k*), rat, and mouse, the *anterior* pair are the larger, and, compared with the cerebral hemispheres, are very voluminous; in the pig, horse, ass, sheep, and deer, the anterior pair are also the larger, but they are of *less* proportional size with the brain; in the cat and stoat the *posterior* pair are the larger; in the monkey they are nearly of *equal* size and present less relative volume, thus approaching very much the characters of the tubercula quadrigemina in the human adult brain. With regard to their position, as before observed, in the lower orders they are situated behind the cerebral hemispheres and are quite exposed, while in the higher orders they are situated underneath the hemispheres, and quite covered by them, as in the human adult brain.

3dly. The cerebellum, or *third cerebral mass* (*figs.* 358, 359, *l*), is remarkable for its great developement; nevertheless, it passes through many grades in the different orders. In the animals before enumerated it is marked externally by transverse striæ and small convolutions, and presents a division into median and lateral lobes. The relative size of the mass itself, and of its different parts, and the number of external striæ, differ according as the animal examined is high or low in the class. In the bat it is within half a line as long as the cerebral hemispheres, the proportions being as 100 : 125; the lateral lobes are just observable, smooth on their surface, but on the large median portion there are two transverse striæ. In the rabbit (*fig.* 358, *l*) its proportional length in the median portion to that of the cerebral hemispheres is as 100 : 207; in the rat, as 100 : 166. The lateral lobes in both are more distinctly developed, and the striæ are better marked. In the horse its pro-

* For the length, by measurement, of the cerebral hemispheres in these different animals, see the table.

portional length is as 100 : 256. In the sheep, as 100 : 232. In the deer, as 100 : 233. The lateral lobes are very evident in all, and convolutions are observable on the external surface, particularly in the horse. In the cat its proportional length is as 100 : 200; in the stoat as 100 : 228. The external convolutions in both are numerous: in the monkey (*fig.* 359, *l*), the proportional length is as 100 : 305; the laminæ are numerous and small, thus approaching very much the characters of the same part in man.

The following is a table, shewing the actual and relative lengths of the cerebral hemispheres and the cerebellum in the Mammalia:—

Animal.	Length of Cerebral Hemisphere	Length of Cerebellum.	Proportions.
Bat....	$2\frac{1}{3}$ lines.	2 lines.	As 100 : 125
Rabbit .	$14\frac{1}{3}$ —	7 —	.. 100 : 207
Rat....	$7\frac{1}{2}$ —	$4\frac{1}{2}$ —	.. 100 : 166
Mouse .	4 —	$2\frac{1}{2}$ —	.. 100 : 160
Horse ..	64 —	25 —	.. 100 : 256
Sheep ..	36 —	$15\frac{1}{2}$ —	.. 100 : 232
Deer...	42 —	18 —	.. 100 : 233
Stoat...	8 —	$3\frac{1}{2}$ —	.. 100 : 228
Cat....	18 —	9 —	.. 100 : 200
Monkey	$30\frac{1}{2}$ —	10 —	.. 100 : 305

On cutting into its substance in many of these animals, the appearance of the arbor vitæ is more or less distinct, similar to the human cerebellum. On its inferior surface is situated its great commissure, the pons Varolii, which first makes its appearance in this class of animals, and, with the exception of the transverse fibres forming it being thinner and fewer in number, particularly in those lower orders of Mammalia where the cerebral hemispheres were small, it presents but little differences from the same part in the human adult brain. This latter remark will equally apply to the fourth ventricle, which has been an object of considerable interest, and which, from being at first an open exposed cavity, is now shut in and concealed.

[On the peculiarities of the brains of the implacental class of Mammalia, see the articles MARSUPIALIA and MONOTREMATA.]

On reviewing these statements of the nervous system in the Mammalia, we observe that the brain now preponderates greatly in bulk over the spinal marrow; this latter is also shorter, and terminates by a true cauda equina. The *first cerebral mass* has now acquired its maximum of developement as regards size; the two portions of which it is composed are united by a large commissure; their exterior surface is convoluted. The *second cerebral mass* is divided into two pairs of ganglia, in which the cavities are obliterated. The *third cerebral mass* has lateral hemispheres developed, striæ and convolutions on their exterior surface, and an important commissure, the pons Varolii, on its inferior surface.

Having thus completed the investigations proposed at the commencement of this paper, it may not in conclusion be without interest and utility to take a very rapid review of the developement of the nervous system in the five large groups of animals in the system of arrangement, as follows:—

a. The nervous system (perhaps) first exists in a molecular form; that is, it is made up of globules dispersed throughout the homogeneous texture of the animal, as in the Acrita, the lower Entozoa, &c.

b. This nervous matter arranged in a longitudinal direction forms filaments. The direction which they assume is that of a ray, or nerve, and a central point, or ganglion; these latter communicate with each other by commissures, which unite them in the form of a ring. This ring is situated around the oral orifice of the animal; it takes the name of the *primary nervous ring;* and from it issue filaments in a radiated manner, as in the Echinodermata.

c. This *oral primary nervous ring* becomes more complicated in itself; ganglions are first developed on its lateral and inferior portions, from which nerves pass off in a longitudinal direction, as in the lower Mollusca, and secondly on its superior surface, as in the higher animals of this class: this superior ganglion is at first proportionally small, as in the Gasteropoda, but afterwards large, and sometimes very large, as in the Cephalopoda. It is the analogue of the tubercula quadrigemina of the higher animals.

d. This *primary nervous ring*, in its most highly developed form, now becomes repeated several times in the body of the animal; first, in an *undetermined* number, as in the Helminthoid Articulata; secondly, in a *determined* number, as in the Entomoid Articulata. These nervous rings are united by longitudinal commissures, and the most anterior one always has a highly developed ganglion on its superior surface. The uniting commissures possess two distinct nervous tracts; respiratory and sympathetic nerves exist, as in the Insecta.

e. These *primary nervous rings* are now become ganglia (brain); the uniting commissures are become primary nervous rings (spinal marrow). First, the ganglia and their commissures are nearly equally developed, and are horizontal, as in the lower Vertebrata; secondly, the ganglionic formation predominates, and its direction, with regard to the commissures, becomes more that of a right angle, as in the higher Vertebrata; thirdly, the predominance of the ganglionic formation is very much increased, and its relative direction is that of a complete right angle, as in the human species.

(John Anderson.)

NERVOUS CENTRES. (Human anatomy).—A nervous centre may be defined as a mass composed of grey and white nervous matter with which nerves are intimately connected. In a physiological point of view it is a centre of nervous action, as nerves appear to conduct to it as well as from it.

The nervous centres in the human subject are the GANGLIONS, the SPINAL CORD, and the BRAIN.

The ganglions are small masses occupying certain situations in the body. They are extremely numerous in the human body, and very variable in shape and size. One great subdivision of them, in man and the mammalia, is connected with the posterior roots of the spinal, and with certain encephalic nerves. Another class belongs to the sympathetic system. In the Invertebrata the nervous system is made up of a series of them variously disposed, with their afferent, efferent, and connecting nerves.

The spinal cord and the brain are peculiar to the great class of vertebrated animals. They may be regarded as compound ganglions, being physiologically resolvable into a series of smaller centres, which are, to a certain extent, independent of each other. Viewed anatomically, they are not so obviously divisible: in the spinal cord, in which the independent influence of separate segments may be most easily demonstrated, no anatomical subdivision is obvious, for the segments are fused together into a cylindroid body, which has a certain relation to the length and muscular activity of the animal. Indications, however, of this composite form of the spinal cord are afforded, in the marked difference of dimensions which certain parts of it present when compared with others, there being always a manifest correspondence between the size of any segment of the cord and the motor or sensitive endowment of that segment of the body which receives its nerves from it. And the case of the common gurnard (*Trigla Lyra*) may be here quoted as a remarkable instance of the developement of distinct gangliform bodies on a portion of the cord, in accordance with a particular exaltation of tactile sensibility.

The brain is much more evidently made up of a series of separate centres or smaller masses, exhibiting sufficiently distinct boundaries on their surfaces, but so intimately connected by what are called *commissural* or uniting fibres, as to manifest the same kind of fusion (although to a less degree) as that noticed in the spinal cord. These gangliform bodies are so readily distinguishable from one another, that from the earliest periods of anatomical investigation each of them has been designated by a distinct name, which is generally derived from some prominent feature of the body itself, or from the name of some familiar object which it has been supposed (often fancifully) to resemble. The aggregate of these bodies is known in popular language by the name of *Brain*, (a word of Saxon origin, sometimes used in the plural); this word, however, anatomically speaking, is applicable only to the great hemispheric lobes which form the largest portion of the whole mass; and the term Encephalon may be more correctly used to denote the whole of the intracranial contents.

It is proposed in the present article to consider the general and descriptive anatomy of these nervous centres severally, beginning with an examination of their coverings.

COVERINGS OF THE NERVOUS CENTRES.

COVERINGS OF THE GANGLIONS. — Every ganglion is covered by a more or less dense layer of white fibrous tissue, similar to that which forms the neurilemma of nerves. It performs precisely the same office for the elements of the ganglions that the neurilemma does for those of nerves; that is, it gives them a mechanical support, and is the medium through which bloodvessels are conveyed to their nervous matter. It is continuous with the neurilemma of the nerves which are connected with the ganglions. It is found in all forms and classes of ganglions, presenting the same essential characters. These bodies are generally surrounded by and imbedded in a considerable quantity of fat, which also involves more or less the nerves that proceed from them.

COVERINGS OF THE SPINAL CORD AND BRAIN. —These are also called the *membranes* of these centres, or the meninges (μηνιγξ, membrana). They are three in number. Those of the brain are continuous with those of the spinal cord, but, as there are certain distinctive characters proper to each, it will be convenient to describe the cerebral and spinal meninges separately. They are, enumerating them from without inwards, the dura mater, the arachnoid membrane, and the pia mater.

The term, mater, μητηρ, originated with the Arabian anatomists, who regarded these membranes as the parents of all others in the body. Galen adopted the word μηνιγξ, and distinguished the first and last of the membranes above enumerated by the adjectives παχυτερη and λεπτη. The Germans use the word *haut*, and designate these membranes as *hautige Hullen des Gehirns und des Ruckenmarkes; die harte Hirnhaut, die härte Ruckenmarkhaut*, the dura mater of the brain and spinal cord; *die Spinnwebenhaut*, the arachnoid; and *die weiche Haut*, the pia mater.

Dura mater.—The dura mater is a dense membrane composed almost exclusively of white fibrous tissue. It has all the characters, physical and vital, of that texture, possessing great strength and flexibility with but little elasticity. It is freely supplied by bloodvessels, and at certain situations, which will be more particularly described by-and-bye, it separates into two laminæ, which inclose prolongations of the lining membrane of the venous system, forming peculiar sanguiferous channels, which are commonly known by the name of *sinuses*. It has an apparent lamellar disposition, from the fact of its fibres being arranged in different planes. In the child a subdivision into two layers may sometimes be easily effected. Some nerves have been demonstrated in the dura mater; a branch of the fifth nerve has been particularly described and delineated by Arnold, as passing in a recurrent course between the laminæ of the tentorium, and Pappenheim has found nervous fibres in the cerebral dura mater derived from the superior maxillary division of the fifth, from the fourth nerve, from the vidian, and probably also from the frontal branch of the ophthalmic.*

* Valentin Repertorium, vol. v. p. 87.

The *spinal dura mater* is in shape adapted to the vertebral canal. It is a hollow cylinder, tapering somewhat at its lower extremity to correspond with the sacral portion of the canal. It adheres very firmly all round the foramen magnum of the occipital bone. From thence it is continued down to the sacrum without forming any adhesion to bone. On the posterior and lateral surfaces it is covered by a layer of soft, oily, reddish fat, which intervenes between it and the inner surfaces of the vertebral laminæ and processes, and in these situations, as well as to a less degree in front, we find a very intricate plexus of veins, some of which are of considerable size. The fatty deposit is most abundant in the sacral region. In front the dura mater adheres by a close areolar tissue to the posterior common ligament, and here of course the adipose tissue is deficient. At the foramen magnum the continuity of the spinal dura mater with that of the cranium is distinct, and here, indeed, the former appears as a funnel-shaped prolongation of the latter; both are, in truth, portions of the same membrane adapted to the difference of shape of the nervous centres with which they are respectively connected.

On the sides the spinal dura mater is perforated by orifices which give exit to the roots of the nerves which arise from the spinal cord. When examined from within, these foramina are found to be arranged in pairs, each pair corresponding to the point of exit of a spinal nerve. The foramen which transmits the anterior root is separated from that which gives passage to the posterior one, by a narrow slip of fibrous membrane. These foramina are slit-like in form, taking the vertical direction. On the outer surface of the dura mater the distinction between them is not evident without dissection, for there the fibrous membrane being prolonged from the margins of the openings around the nerves, the sheaths thus formed coalesce and surround both roots. The number of these orifices is of course the same as that of the roots of the nerves which pass through the dura mater.

The internal surface of the spinal dura mater is perfectly smooth and moist in the healthy state, owing to its being lined by the parietal layer of the arachnoid membrane. In the intervals between the orifices for the transmission of each pair of spinal nerves, it receives the pointed attachments of the ligamentum denticulatum, to be described more fully by-and-bye.

It is evident from the preceding description that the spinal dura mater cannot perform the office of a periosteum to the osseous walls of the spinal canal, for at every point it is separated from them by texture of a different kind, and, moreover, the vertebræ are provided with a distinct periosteum. The prolongations of dura mater over the nerves at each of the intervertebral foramina serve to fix that membrane at the sides throughout the whole extent of the vertebral canal, so as to prevent its lateral displacement. At the lower extremity of the sacral canal the dura mater ends in a blunt point, and from this certain processes may be traced towards the coccyx. Of these the central one is continuous with the filiform prolongation from the pia mater, which is inserted into the inferior extremity of the dura mater, and is implanted into the last bone of the coccyx. The thread-like processes which are seen on each side are the sheaths of the last sacral nerves and of the coccygeal nerve, which pass some distance in the canal before they reach the foramina for their transmission outwards.

It is easy to convince oneself that the spinal dura mater is far larger than would be necessary for the reception of the cord. When the fluid immediately surrounding this organ has been suffered to escape, the dura mater appears quite loose, flaccid, and wrinkled. By blowing air or injecting water into its canal, it may be rendered tense again. This looseness of the dura mater is most conspicuous at its lowest part, in the lumbar and sacral regions, where it forms, as Cruveilhier says, "autour de la queue de cheval une vaste ampoule, qui parait n'avoir d'autre utilité que de servir de reservoir au liquide cephalo-rachidienne."

The dura mater adapts itself, in point of size, to the varying dimensions of the spinal canal in its different regions, which again appear to be influenced by variations in the dimensions of the spinal cord. Thus, it swells in the cervical and in the lumbar region, at both which places there are corresponding enlargements of the cord. Its most contracted portion is that which occupies the dorsal region.

Cranial dura mater.—The dura mater of the cranium differs in one leading circumstance from that of the spine,—namely, that it forms a periosteum to the inner surface of the cranial bones. We find it, therefore, very closely adherent to the whole interior of the cranium, and the free communication between the vessels of the dura mater and those of the bones serves materially to enhance the connexion between this membrane and the osseous surface. At some situations the adhesion is so very intimate that we experience great difficulty in attempting to separate the fibrous membrane from the subjacent bone. On the roofs of the orbits, the wings of the sphenoid bone, the petrous portions of the temporal bones, the margin of the occipital foramen, and opposite the sutures, the adhesion is very intimate.

This adhesion of the dura mater to the bones is found also to vary in degree at different periods of life. It is very intimate in old age, so much so that, in removing the calvaria, layers of bone often chip off, remaining in connexion with the fibrous membrane. In the adult, such a degree of adhesion as would give rise to this effect, ought to be regarded as morbid. In the young subject, while ossification and growth are going on, the adhesion is very intimate, so that in them great difficulty is experienced in removing the calvaria. Doubtless this intimate adhesion at this early period of life is due to the active share which the dura mater takes in conveying the material of nutrition and growth to the cranial parietes.

The cranial dura mater is not a simple bag. From its internal surface partition-like processes pass inwards, which serve to separate certain subdivisions of the encephalon. These are, the *falx cerebri*, the *tentorium cerebelli*, and the *falx cerebelli*.

The *falx cerebri* is a process of fibrous membrane corresponding to the mesial plane and lying in the great median fissure of the brain, where it separates the lateral hemispheres from each other. Its shape is falciform; its superior convex border corresponds to the frontal and sagittal sutures, and encloses the great longitudinal sinus; its inferior border is concave and much shorter than the superior, and corresponds to the superior surface of the corpus callosum, which connects the hemispheres of the brain. In front the falx is very narrow and almost pointed; it embraces the *crista galli* of the ethmoid bone, which appears to be enclosed between its layers. As the falx proceeds backwards it increases considerably in depth; its superior edge may be traced back to the internal occipital protuberance; its inferior edge terminates at a point corresponding to the middle line of the posterior margin of the corpus callosum. The falx cerebri contains within it, along its posterior border, a large vein, which is called *the inferior longitudinal sinus*.

The falx cerebri is continuous at its posterior border on each side with the *tentorium cerebelli*. This process is nearly horizontal in its direction; it forms a vaulted roof to a cavity (the floor of which corresponds to the occipital fossæ) in which the cerebellum is lodged. Its upper surface is convex on each side of the attachment of the posterior extremity of the falx cerebri: it supports the posterior lobes of the brain. The inferior surface is adapted to the upper convex surfaces of the cerebellar hemispheres. Its posterior and outer edge adheres to the occipital bone and to the posterior border of the petrous portion of the temporal bone, reaching as far inwards as the posterior clinoid processes of the sella Turcica. The occipital portion of this edge contains a considerable part of the lateral sinus (*fig* 362, *e*) and that portion which adheres to the petrous bone contains the superior petrosal sinus. The anterior or inner margin of the tentorium is concave and free in the greater part of its extent; it forms the posterior and lateral boundary of a large opening (which the sella Turcica completes in front), through which the crura cerebri and other parts connected with them pass. This margin is attached by its anterior extremities to the anterior clinoid processes, to reach which it crosses the posterior border. The crossing of these two edges at a point external to the sella Turcica gives rise to the formation of a little triangular space, the base of which corresponds to the sella Turcica; its outer angle is perforated for the transmission of the third pair of nerves, and its anterior one for that of the fourth pair.

From the inferior surface of the tentorium cerebelli at its posterior edge, a short and thick fold of very slight depth descends to the posterior edge of the foramen magnum. This is the *falx cerebelli*; it corresponds to the median notch between the hemispheres of the cerebellum. Its anterior border is slightly concave. Two veins called *occipital sinuses* are contained in it.

The internal surface of the cranial dura mater presents the same smooth appearance as we have noticed in the spinal membrane of the same name. We observe, however, an exception to this on each side of the line along the great longitudinal sinus. Here it is very common to find the membrane presenting a peculiar cribriform appearance, which occupies a space of from half an inch to two inches in length and not more than a quarter of an inch in breadth, but exhibiting great difference in various subjects as to the number and depth of the foramina or depressions upon which the sieve-like structure depends. These depressions are caused by the presence of little bodies which grow from the layer of arachnoid that covers the brain, *glandulæ Pacchioni*, which will be described by-and-bye. The anatomist may expect to find in a large proportion of adult brains a greater or less degree of adhesion between these parts of the dura mater and the edges of the hemispheres of the brain.

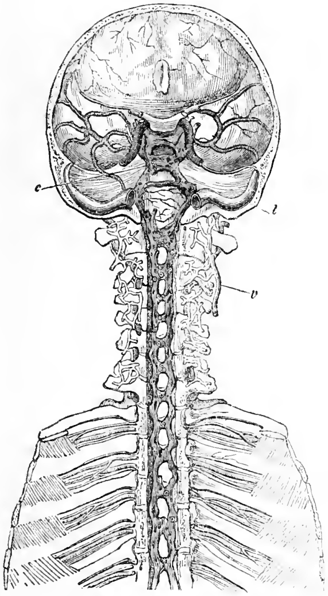
The dura mater is perforated by numerous orifices for the transmission of the encephalic nerves. It adheres firmly to the border of each of the foramina in the cranial bones, and is partly continued in the shape of neurilemma over the nerve that escapes through it. In the case of the optic nerve a strong fibrous sheath is prolonged from the dura mater, and at the same time that membrane appears to become continuous with the periosteum of the orbit, as if it had, opposite the optic foramen, split into two layers, one of which formed the sheath of the optic nerve, and the other applied itself to the interior of the orbit, forming a periosteum to the walls of that cavity.

Of the arteries and veins of the dura mater.—The disposition of the bloodvessels of the dura mater, both of the spine and of the cranium, deserves a special description. The former membrane derives its arteries from the numerous vessels which take their rise close to the spinal column in its various regions. These are ramifications of the abdominal and thoracic aorta or of their large primary branches. In the neck the deep cervical, the occipital, and the vertebral arteries send in numerous branches, in the back the intercostal arteries, and in the loins the lumbar arteries. These vessels pass in at the vertebral foramina, and send branches to the spinal membranes as well as to the bones themselves.

The blood which is returned from the spinal cord and its membranes, as well as from the vertebræ, is poured into a very intricate plexus of veins which surrounds the dura mater on its lateral and posterior surfaces, ramifying among the lobules of soft fat by which the exterior of that membrane is invested. This plexus is less intricate in the dorsal than in the cervical or lumbar regions; it communicates very freely with the plexus of veins which lies on the exterior of the vertebral laminæ and processes (the *dorsi-spinal veins* of Dupuytren).

In front of the dura mater and situate between the outer edge of the posterior common ligament of the vertebræ and the pedicles, we find two remarkable venous sinuses which extend the whole length of the vertebral column, from the occipital foramen to the sacral region (*fig.* 360).

Fig. 360.



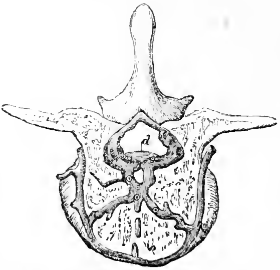
Spinal sinuses viewed from before.
(After Breschet.)

The anterior part of the basis cranii and the face have been removed, as also the bodies of the vertebræ.

l, lateral sinus descending to form its junction with the jugular vein; *c*, cavernous sinus; *v*, vertebral artery, the longitudinal sinuses with their transverse connecting veins, lying immediately behind the bodies of the vertebræ. The inferior petrosal and the cavernous sinuses appear like continuations of them within the cranium, and the transverse and circular sinuses are analogous to the transverse spinal branches.

These veins are loosely covered by a thin process, which is prolonged from each margin of the posterior common ligament, and which is sufficiently transparent to allow them to be seen through it without removing it. They have been known since the time of Fallopius, and were described by Willis as the *longitudinal spinal sinuses*. In calibre they present many inequalities, being dilated at one part and constricted at another, according to the number and size of the vessels which communicate with them. The sinuses of opposite sides run parallel to each other and communicate by cross branches, which pass between the posterior surface of the body of each vertebra and the posterior common ligament. These cross branches present the same characters as the sinuses themselves, being of variable calibre, and presenting the greatest degree of dilatation at their middle. At this point these branches receive veins which emerge from the spongy texture of the bodies of the vertebræ (*basi-vertebral veins* of Breschet) (*fig.* 361, *d*). The vertebral sinuses diminish in

Fig. 361.



Basi-vertebral veins, converging from the spongy structure of the body of the vertebra.

size at the highest part of the vertebral canal, and passing through the anterior condyloid foramina, communicate with the internal jugular veins. In the sacral region they diminish considerably likewise, and are lost in becoming continuous with the lateral sacral veins and other small veins in that region; and they communicate with the deep and superficial vertebral veins in the neck, with the intercostal veins in the back, and with the lumbar ones in the loins. They evidently differ from the sinuses of the cranial dura mater in not being enclosed between two layers of fibrous membrane as those vessels are.

Bloodvessels of the cranial dura mater.—The bloodvessels of the cranial dura mater are much more numerous than those of the spinal, in consequence, no doubt, of that membrane performing the office of a periosteum to the cranial bones. The arteries are derived from numerous sources; in front from the ophthalmic and ethmoidal arteries, in the middle from the internal maxillary artery by the *middle meningeal*, which enters the cranium at the foramen spinosum, and by small branches from the internal carotid which have been called *inferior meningeal* arteries. Posteriorly the vertebral, the occipital, and the ascending pharyngeal supply branches which go by the name of *posterior meningeal arteries*.

The veins of the dura mater are formed similarly to those in other parts, being derived from radicles which take their rise in the membrane itself as well as from the osseous walls of the cranium, from the diploïc veins of those bones. (See Bone, *figs.* 187, 188, vol. i.) All of them, with the occasional exception of one or two which accompany the middle meningeal artery and pass out at the foramen spinosum, pour their blood into the great venous canals enclosed between the laminæ of the dura mater, which are called *Sinuses*.

The sinuses of the dura mater.—At certain situations, processes of the inner membrane of the venous system are included in canals formed by the separation of the laminæ of the dura mater. The channels that are thus formed for the passage of the venous blood do not admit of being dilated beyond a certain size, and in this consists an important peculiarity in the venous system within the cranium. These channels empty themselves into the internal jugular vein, which thus forms almost the sole channel by which the venous blood is returned from the brain and its membranes as well as in a great measure from the bones of the skull. And thus is explained the rapid influence which is produced upon the brain by any impediment to the passage of the blood through the superior vena cava.

It is important to notice that the sinuses communicate with and receive blood from certain external veins which carry blood derived from parts exterior to the cranium. Among these may be enumerated the ophthalmic vein, and several small veins in the neighbourhood of the mastoid and condyloid processes, and in the parietal bones.

The following sinuses may be described.

The superior longitudinal sinus. — This sinus corresponds to the superior margin of the falx cerebri. It commences very narrow by one or two small veins from the dura mater in the vicinity of the crista galli and cribriform plate of the ethmoid bone. Thence it proceeds backwards, gradually increasing in calibre, and it terminates a little above the internal occipital protuberance by communicating with a small cavity or reservoir, situated between the layers of the dura mater there, which is called *Torcular Herophili.* If a vertical section of this sinus be made in the transverse direction, it will be seen to be triangular in shape, the apex corresponding to the falx, the base slightly curvilinear and lodged in the groove which passes along the median line of the cranial vault. When the sinus is laid open in its length by slitting up its superior wall, we find that its sides are perforated by a great number of minute orifices, which are the openings of veins passing into it from the dura mater and from the brain itself. These veins pass into the sinus chiefly at right angles to it, or in the direction from behind forwards; a few, situate in front, enter the sinus from before backwards. In the interior of the sinus we observe little bands *(trabeculæ* of Haller, *chordæ Willisii),* stretching across from right to left, connected only with the lateral walls and leaving a free space above and below them. These bands are numerous, and various as regards breadth. Haller has seen them so numerous that they appeared like a septum dividing the sinus into two portions, of which the superior was the larger.

The walls of the sinus, towards its inferior angle, have frequently a cribriform appearance, which puts on somewhat the aspect of erectile tissue. There is no appearance of valves in the interior of the sinus; frequently, however, the oblique entrance of a small vein into the sinus produces a fold near the venous aperture, which, under the retrograde pressure of the column of blood, might close the orifice, and probably, when the veins open into the sinus from behind forwards, they may be protected from the regurgitation of the blood by this mechanism.

Several of the small bodies, previously alluded to by the name of Pacchionian glands, project into the cavity of the sinus through apertures in its wall. They appear as if they had worn their way by pressure and friction through the walls of the sinus, and it is here that the appearance of an erectile structure is most manifest. We cannot suppose that these bodies are bathed in the blood of the sinus, but rather that they push the lining membrane of the sinus before them. It has been supposed that these bodies are natural structures destined to perform a mechanical office somewhat on the principle of the ball-valve, but they are frequently absent altogether, and when present they have no constant relation to the venous orifices.

The inferior longitudinal sinus (sinus inferior falcis) is a small vein lodged in the inferior part of the falx cerebri, running parallel to and a little above its inferior margin for about the two posterior thirds of its length. It gradually increases in calibre from before backwards, being formed by tributary veins from the falx; it opens into the strait sinus.

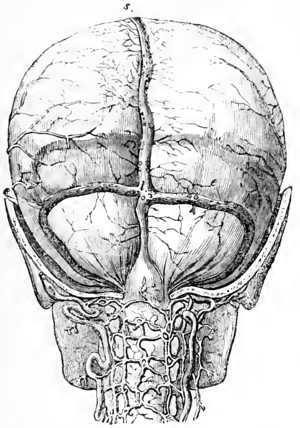
The strait sinus corresponds to the middle line, at the place where the falx cerebri unites with the tentorium cerebelli. It seems to be enclosed between the layers of the former. Like the other large sinuses, it presents in its section the form of a triangle, whose base is inferior. Its direction is from before backwards and a little downwards, with a slight degree of curvature corresponding to that of the tentorium. It corresponds at its commencement to the space between the posterior reflected portion of the corpus callosum and the quadrigeminal bodies, and here it receives two large veins *(venæ magnæ Galeni),* which carry the blood from the interior of the ventricles, and a third vein, the inferior longitudinal sinus. It opens into the conflux of the sinuses or torcular by a round opening or sometimes by two openings, separated by a slip of fibrous membrane. This sinus likewise receives veins from the inferior surface of the posterior and middle lobes of the brain, and from the superior surface of the cerebellum.

At the posterior extremity of the straight sinus we find a reservoir somewhat polygonal in shape, which corresponds to the occipital protuberance; this is called the *Torcular Herophili,** (the press of Herophilus,) the conflux of the principal sinuses of the dura mater; it has six openings, one for the superior longitu-

* This absurd name might with great advantage be discarded, for it seems quite uncertain what precise part Herophilus intended to apply it to. The term proposed by Cruveilhier is much better, *the occipital conflux of the sinuses.* Various other names were applied to it formerly, such as *Lacuna, platea, pelvis, laguncula.*

dinal sinus above; one for the straight sinus in front; two for the lateral sinuses on each side; and two for the occipital sinuses inferiorly (*fig.* 362, *t*).

Fig. 362.



Posterior part of the cranium removed, to shew the dura mater and the superior longitudinal, and the lateral sinuses, with the torcular Herophili.

e, lateral sinus; *t*, torcular Herophili; *s*, superior longitudinal sinus.

Lateral sinuses.—From each side of the conflux of the sinuses, there proceeds in a somewhat serpentine course outwards, downwards, and forwards, a wide canal, the largest of the sinuses, which conveys the blood from the torcular to the internal jugular vein. A groove exists on each side of the internal occipital protuberance, for the reception of this sinus, which marks the occipital bone, the mastoid portion of the temporal, and a small portion of the occipital bone again. In a great portion of their course, the lateral sinuses correspond to the posterior margin of the tentorium cerebelli, as far forwards as the mastoid portion of the temporal bone. Here each sinus winds downwards to reach the jugular foramen in the posterior lacerated opening. These sinuses are never equal; that of the right side being, with few exceptions, the larger, a circumstance which Vicq d'Azyr, Söemmering, and Rudolphi attributed to the fact that most persons sleep on the right side, on which account the blood is apt to accumulate to that side. They are more capacious at their termination in the jugular veins than at their commencement from the torcular. The inner surface of this sinus is like that of all the others; it is not, however, traversed by any of the bands which are found so numerous in the longitudinal sinus. Cruveilhier states that he once saw in the horizontal portion of this sinus, a few of the *Pacchionian* bodies.

In its course each lateral sinus receives veins from the inferior surface of the brain and superior of the cerebellum; it also receives the superior petrosal sinus near the base of the petrous portion of the temporal bone. A large mastoid vein communicates with this sinus and penetrates to the exterior, where it forms one of the principal sources of the occipital vein, thus establishing a free and direct communication between the circulation within and that without the cranium.* Near the jugular foramen the lateral sinus receives the inferior petrosal.

None of the sinuses has been more frequently the seat of inflammatory disease than the lateral. Being the principal channel for the return of the venous blood from the interior of the skull, a slight morbid action within them can scarcely fail to induce a material derangement of the cerebral circulation, and the nearness of their position to the cerebellum and to the posterior lobes of the brain renders it very unlikely that those parts would escape participating in any acute disease which might arise within it.

Occipital sinuses.—These are small veins lodged between the layers of the falx cerebelli. They collect the blood from the dura mater and from the cranial bones in the immediate vicinity of the posterior margin of the foramen magnum, and from thence they pass upwards and inwards to open into the lower part of the torcular. Cruveilhier suggests that the direction and position of the occipital sinuses are best indicated by describing them as being the cords of the arcs which the lateral sinuses form.

Petrosal sinuses.—These sinuses are so named from their connection with the petrous portion of the temporal bone. The *superior* petrosal sinus corresponds, on each side, to the posterior superior edge of the petrous bone, along the three outer fourths of which a groove exists for its reception. This groove is interrupted in front by a depression in which the fifth nerve is lodged, so that at this place that nerve lies between the sinus and the bone. The superior petrosal sinus is about large enough to contain an ordinary sized surgeon's probe. It communicates with the lateral sinus posteriorly and with the cavernous sinus in front, and in its course it receives several small veins from the dura mater in the middle fossa of the cranium. It receives a vein from the anterior portion of the corresponding hemisphere of the cerebellum, and also, sometimes, one from the inferior surface of the brain. Small veins from the pons Varolii empty themselves into its anterior extremity.

The *inferior* petrosal sinuses also form an additional channel of communication between the lateral and cavernous sinuses. They are larger but shorter than the superior. In situation they correspond to the interval between the petrous bone and the occipital. They open into the inferior portion of the lateral sinus just before it unites with the jugular vein.

Transverse sinus.—This sinus establishes a communication between the petrosal and

* Cruveilhier, An. Desc. t. iii. p. 268.

cavernous sinuses of opposite sides across the basilar process of the occipital bone. Sometimes there are two running parallel to each other. Cruveilhier states that the capacity of this sinus is much greater in old than in young subjects.

Cavernous sinuses.—In point of shape these sinuses differ considerably from all the other sinuses of the dura mater. They are venous reservoirs, situated on each side of the sella Turcica, from which they are separated by the internal carotid arteries. Their name is derived from the spongy appearance which they present in their interior, owing to the existence of some filaments within them, which, by their interlacement with each other, form a reticular texture there. It was formerly supposed that the carotid arteries lay in the cavity of these sinuses and were bathed by their blood; but it is easy to demonstrate by a little careful dissection that the inner membrane of the sinus adheres loosely to the outer wall of the artery, and that the sixth nerve passes between them. In the outer wall of each cavernous sinus there are channels for the reception of those nerves, which pass from the cranium into the orbit. These are the third nerve which is placed highest up, the fourth nerve which holds the next place, and the ophthalmic portion of the fifth. The cavernous sinus receives at its anterior extremity the ophthalmic vein, which collects the blood from the eye-ball and other structures within the orbit, and which communicates also with the angular vein and with the frontal vein. (Hence the injected state of the vessels of the eye-ball when the brain is congested, as in fever.) Veins from the inferior surface of the anterior lobes of the brain also open into it, also some from the middle lobe and from the dura mater. Posteriorly it communicates with both the petrosal sinuses, and veins from the cranial bones open into its superior wall.

Circular sinus.—A communication is established between the cavernous sinuses by means of the *circular* or *coronary* sinus which embraces the pituitary body, one portion lying in front of it and the other behind it, both opening by a common free orifice into the right and left cavernous sinuses. The posterior portion of the circular sinus is much larger than its anterior portion. Its size is much greater, according to Cruveilhier, in old subjects than in young ones. It receives small veins from the pituitary body, and also from the sphenoid bone and from the dura mater.

It is impossible to examine this complicated arrangement of venous channels in connexion with the dura mater of the brain without admiring the beautiful provision which it affords against the undue accumulation of blood in the venous system within the cranium. In the first place, we observe that these veins do not admit of dilatation beyond a prescribed extent, by reason of their being enclosed between layers of an inelastic and inextensible membrane. Next, we remark the safety provision which is afforded by the frequent communication between them, so that if one channel were altogether closed or materially contracted, there are many others by which the blood could return. Nor is a local congestion likely to take place to any extent, for such is the freedom of communication between the sinuses and the veins of the exterior of the cranium, that (all being devoid of valves) an overflow would readily be received by the latter without the least impediment. Lastly, we learn the great importance and value of local depletion as an agent for relieving vascular fullness within the head, owing to the free communication between the extra- and the intra-cranial circulation, and especially of the veins; and we may infer from anatomy that local depletion would most probably be more serviceable than general, for although the latter would diminish the amount of the mass of circulating fluid, it would not affect the relation between the venous and arterial systems, whilst it is evident that the former must affect the venous system more directly than the arterial. Moreover, the free communication between the circulation within and that without the cranium may explain somewhat the advantage that is often derived from the application of an intense cold to the external surface of the head.

Of the pia mater. (Tunica intima vel *vasculosa.)*—The pia mater is the most internal membrane of those which have been enumerated as belonging to the spinal cord and brain.

Pia mater of the spinal cord.—This membrane stands in precisely the same relation to the spinal cord as the neurilemma does to the nerves; and as long as the spinal cord could be, as it formerly was, regarded merely as a bundle of nervous fibres, the analogy of this membrane to the nervous sheath would be perfect. It is composed almost entirely of white fibrous tissue; it closely invests the cord and supports the minute bloodvessels which carry the nutrient fluid to it. Not only does it thus form a complete sheath to the cord, but it likewise sends in processes which dip into the anterior and posterior median fissures of that organ. That which passes into the anterior median fissure is a true fold or duplicature of the pia mater; but the posterior fissure, which is much narrower than the anterior, is occupied only by a single and extremely delicate layer, which at some parts almost entirely disappears, and seems to consist merely of a few minute capillary vessels. The pia mater becomes continuous with the neurilemma of the roots of the nerves on each side of the cord, and at its inferior extremity it tapers in accordance with the shape of the spinal cord, and is prolonged as a delicate thread which is inserted into the extremity of the dura mater. This prolongation is quite gradual, so that at the upper part it encloses a portion of the medullary substance of the cord; in the greater part of its extent, however, it is merely a membranous thread, and, therefore, goes by the name *filiform prolongation* of the pia mater *(filum terminale)*. The late Dr. Macartney used to regard it as highly elastic, but my friend Mr. Bowman has called my attention to the fact that it consists almost entirely of white fibrous tissue, which cannot confer elasticity. And if a portion removed from the cord be stretched, it will be found to possess very little elasticity; but if the cord be held up by the filiform prolongation, and a slight jerking movement be communicated to it, it may be made to dance about as if by the elastic reaction of the filliform process. The movement which may be thus produced is very well calculated to deceive, and Dr. Macartney must have founded his opinion upon that experiment alone, omitting to try the effect of stretching a detached portion of the process. The fact is that when the cord is suspended in this way, the pia mater becomes stretched, and its anterior and posterior portions are approximated and the cord flattened; when it is raised with a jerk, this tension of the pia mater is diminished, and the cord returns to its previous form until it falls again, stretches the pia mater, and becomes once more flattened, producing a degree of reaction which favours its elevation, but which alone would be insufficient for that purpose. Thus it appears that the elastic reaction, which Dr. Macartney attributed to the filiform process, is in reality due to the compression and consequent flattening of the cord by the tension of the pia mater. It should be stated, further, that this process is not formed of pia mater alone, but also of a continuation of the ligamentum denticulatum on each side to be described by-and-bye.

The pia mater is abundantly supplied by bloodvessels, many of which are extremely tortuous. These vessels are derived from the anterior and posterior spinal arteries. Along the anterior surface of the spinal cord in front of the anterior median fissure there is a narrow band of fibrous tissue which is stretched across this fissure like a bridge, and occupies its whole length. No such arrangement exists on the posterior surface.

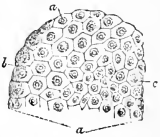
The pia mater of the spinal cord possesses considerable strength and density. The nervous matter may by pressure be squeezed out of it, leaving a hollow cylindrical membrane, or it may be dissolved out by the action of liquor potassæ. In the quite recent state, while the cord is as yet firm, the pia mater may be readily dissected off, its adhesion to the cord being through the medium of numerous exceedingly minute capillary vessels. On its exterior the pia mater adheres to the visceral layer of the arachnoid membrane by means of a loose fibrous tissue.

Pia mater of the brain.—In tracing the pia mater of the spinal cord upwards, it will be found gradually to become much thinner and more delicate as it passes from the medulla oblongata to the hemispheres of the cerebellum and cerebrum. In connexion with these latter parts it becomes of extreme tenuity, and owes its physical tenacity chiefly to the intimate connexion of the visceral layer of the arachnoid membrane with it. The cerebral pia mater is almost exclusively composed of numerous ramifications of minute vessels which are accompanied by white fibrous tissue in small quantity. These vessels divide and subdivide to the last degree of minuteness, and are admirable objects for examining the structure of capillary vessels. The pia mater adheres closely to the whole surface of the brain, cerebellum, and connecting parts, and numberless vessels pass from it into the nervous substance in contact with it. On the surface of the brain it dips down into the sulci or furrows between the convolutions, and adheres to the superficial grey matter. Wherever there is a depression or fissure of the brain, the pia mater is found dipping into it. It likewise sinks into the fissures between the laminæ of the cerebellum.

We shall obtain, however, a very inadequate notion of the extent of the pia mater, if we confine our examination of it to the exterior of the brain and cerebellum. At certain situations this membrane is continued into the cavities or ventricles of these organs, where it doubtless fulfils some office connected with the support and nutrition of certain parts of them. These situations are four in number, as follow: on each side, the fissure between the crus cerebri and the middle lobe of the brain, behind, the transverse fissure between the cerebellum and cerebrum, and, lastly, the inferior extremity of the fourth ventricle.

Choroid plexuses of the lateral ventricles.—These are apparently folded processes of the pia mater which enter the inferior part of the lateral ventricles on each side, and are continued upwards and forwards to their middle portions, where they become continuous with each other in the foramen commune anterius, and with a middle process, the velum. Each choroid plexus forms a somewhat cylindrical process, which, when traced from below upwards and from behind forwards, will be found to follow the direction of the lateral ventricle as far forwards as the apex of the horizontal portion of the fornix, gradually diminishing in thickness, and assuming the character of a simple membranous expansion. It projects freely into the cavity of the ventricle, having no connection with the walls of that cavity excepting along the margins of the fissure, at which it enters, where the membrane of the ventricle adheres to it, being probably reflected upon it.

Fig. 363.



Choroid plexus of lateral ventricle in the Sheep, shewing a villous process, highly magnified, and the epithelium.

(After Valentin.)

a, villus; *b*, epithelium; *c*, nucleus of epithelium.

Very numerous and tortuous bloodvessels are contained in these processes, forming a plexus which has given name to the folds themselves.

The surface of each choroid plexus presents many slight projections or folds resembling villi, in which are contained loops and plexiform anastomoses of minute vessels, very similar to the arrangement of the vessels of the villous processes of the chorion of the ovum, or those of the tufts of the placenta. These vessels are surrounded by an epithelium which has much the appearance of that of serous membranes. From the great number of these vessels and from the delicate nature of the epithelial covering which surrounds them, it is plain that the choroid plexuses are well suited either for the purpose of pouring out fluid or of absorbing it.

Fig. 364.

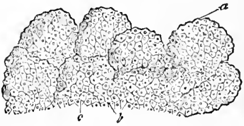
a, epithelium; *b*, bloodvessels.
(*After Valentin.*)

The epithelium may be best seen by examining the edge of a fold. It becomes very distinct when acted upon by acetic acid. As its particles are very delicate and consist only of a single layer, they are easily detached. The cells of epithelium are most of them six-sided, and contain a clear nucleus, or several minute granules. Valentin states that cilia may be seen playing upon this surface, especially in the embryo. I have observed the peculiar punctiform or spiniform formations to which he alludes, which look like the remains of former vibratile cilia.

Velum interpositum. (*Toile Choroidienne,* Vicq d'Azyr.)—The choroid plexuses are connected to each other by the *velum interpositum,* which is a triangular fold of pia mater that passes in at the transverse fissure between the upper surface of the tubercula quadrigemina and the posterior reflected portion of the corpus callosum. This process is continuous with the pia mater of the inferior surface of the posterior lobes of the brain, and with that of the superior surface of the cerebellum, and it therefore consists of two laminæ; as it passes forwards, it sends downwards a little process which embraces the pineal body; it forms the roof of the third ventricle, being interposed between that cavity and the fornix, (hence its name,) and at its sides as well as its apex its continuity with the choroid plexuses may be readily demonstrated. At its anterior extremity it corresponds to the foramen commune anterius. The velum interpositum is best exposed in the dissection from above downwards by removing carefully in succession the corpus callosum and the fornix. In raising the velum itself, in order to disclose the cavity of the third ventricle, it is necessary to be very careful, as from the intimate connexion which the pineal body has with it towards its base, that body may be readily disturbed from its position.

Choroid plexuses of the fourth ventricle.—The choroid plexuses of the fourth ventricle are two small processes of pia mater united along the median line, presenting the same villous character as those of the lateral ventricles. These folds seem as if they had been pushed up into the fourth ventricle by the lower laminæ of the inferior vermiform process. Their position may be best seen by opening the fourth ventricle from above, where they will be found lying on each side of that portion of the median lobe of the cerebellum which stops up the inferior extremity of the fourth ventricle. These plexuses are in every respect similar, as far as regards structure, to the larger ones which are found in the lateral ventricles, and, like them, exhibit a delicate epithelium upon their surface. Upon the centre of each epithelium cell Valentin states that a pigment corpuscule is deposited. (*Fig.* 365.)

Fig. 365.



A highly magnified villus of the choroid plexus of human cerebellum. (*After Valentin.*)

a, the villus; *b*, the epithelium cells; *c*, the nuclei.

These internal processes of the pia mater contain minute crystalline formations, a kind of very fine sand, which, however, is not constantly present in all brains.

The grains are deposited in the meshes of the vascular plexuses. Sometimes they accumulate in masses so as to be visible to the naked eye or easily recognized by the touch. In general, however, they are microscopic, in form globular, and connect themselves with the minute vascular ramifications like little bunches of grapes. They are found principally in the choroid plexuses of the lateral ventricles, and in that portion of the velum interpositum which embraces the pineal body. In the former they are most numerous at that part which was called by the Wenzels *glomus*, where the choroid plexus turns up from the inferior cornu into the horizontal portion of the lateral ventricle.* As regards chemical composition this

* See Van Ghert de plexubus choroideis, Utrecht. 1837; Valentin, in Soemmering Anat., and

sabulous matter consists chiefly of phosphate of lime with a small proportion of phosphate of magnesia, a trace of carbonate of lime, and a small quantity of animal matter.

The pia mater adheres very closely to the surface of the brain, coming for the most part into contact with grey matter. When a portion of it is raised carefully in a fresh brain, numberless extremely minute bloodvessels are seen passing from it into the cerebral substance. These are the principal nutrient vessels of the brain. On its outside the pia mater adheres partially to the arachnoid membrane. At those points which correspond to the convex portions of the convolutions the adhesion of arachnoid to pia mater is close; but at other places the latter membrane separates completely from the former.

The pia mater of the brain differs from that of the spinal cord in its great delicacy and tenuity; it wants the strength and density of the latter membrane. This is owing to its being composed almost entirely of extremely minute and delicate bloodvessels, whilst the spinal membrane consists chiefly of white fibrous tissue. The bloodvessels of the former are infinitely more numerous than those of the latter, and the reason of this probably is that the cerebral membrane is chiefly in contact with grey matter, which requires a great quantity of blood, but the spinal membrane immediately embraces white matter, which is much less vascular.

It is important, in a pathological point of view, to notice that this membrane is the medium of nutrition, not merely to the nervous matter of the brain and cord, but also to the arachnoid membrane which is immediately adherent to it, and to which it bears the same relative position as the sub-serous areolar tissues elsewhere to their respective serous membranes. Hence the difficulty, if not the impossibility, of adopting distinctions which systematic writers endeavour to make out between arachnitis and superficial inflammation of the brain. It is physically impossible that there shall be arachnitis without serious disturbance of an inflammatory kind in the circulation of the pia mater, nor can this exist without affecting the superficial layers of the grey matter of the convolutions. It may, therefore, be confidently affirmed that arachnitis, when affecting that portion of the arachnoid membrane which covers the hemispheres of the brain, is synonymous with inflammation of the superficial layers of the grey matter of the convolutions. Whatever be the point of departure, it seems impossible that inflammation of the one can exist without a similar and equal affection of the other. And thus we may explain the apparently anomalous statement of authors that inflammation of the arachnoid should give rise to a more violent train of symptoms than deep-seated inflammation of the brain. The real difference is, not between membranous and cerebral inflammation, but between an inflammatory affection of the superficial grey matter of the convolutions, the great source and seat of the physiological activity of the brain, and a similar morbid action of the more central white substance, the function of which is in a certain sense subservient to that of the superficial grey matter.

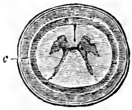
Of the arachnoid membrane.—This membrane is intermediate to those already described. We have preferred giving the description of it last, because to understand it demands an acquaintance with the details of both those membranes.

The arachnoid is a great serous membrane pervading the entire cranio-spinal cavity. Its parietal layer adheres intimately and inseparably to the inner surface of the dura mater both cranial and spinal, and its visceral layer is attached to the outer surface of the pia mater.

In point of structure and general disposition the arachnoid membrane resembles other serous membranes, so much as to render it inexpedient to enter into any minute comparison of them. It will only be necessary to refer to such peculiarities of arrangement as may arise from the anatomical characters of the nervous centres with which it is connected.

Spinal arachnoid.—The serous character of the spinal arachnoid is best seen by examining a transverse section of the spinal cord and its membranes. If the section be made across the interval between two sets of spinal nerves, the visceral and parietal layers of the membrane may be seen in contact with each other; the parietal layer closely attached to the dura mater, the visceral layer adherent to the pia mater of the spinal cord so loosely as to leave a considerable space between it and the outer surface of that membrane.

Fig. 366.



Transverse section of spinal cord and its membranes between the fifth and sixth cervical nerves. (After Arnold.)

v, visceral layer of arachnoid membrane; *s*, sub-arachnoid space; *c*, arachnoid cavity.

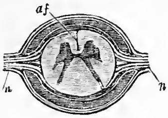
We may here notice an important distinction which the student of this portion of anatomy will do well to note particularly, namely, that the space between the two layers of arachnoid membrane is the *arachnoid bag or sac*, in which it is very rare for any fluid to accumulate; and that that between the visceral layer of the arachnoid and the pia mater is the *sub-arachnoid cavity*, in which, as will be shown by-and-bye, a considerable quantity of fluid exists in the natural state.

When the section is made on a level with the nerves as they emerge through the dura mater, we may notice the manner in which the arachnoid membrane is prolonged upon the nerves in the form of a loose sheath, forming little

Bergmann, über die innern Organisation des Gehirns. The last author states that he has seen the sandy deposit excessive in connexion with mental derangement.

culs-de-sac at the orifices through which the nerves escape.

Fig. 367.



Transverse section of the same on a level with the fifth cervical nerves. (After Arnold.)

The same parts are displayed as in the last figure, and the reflection of the arachnoid at the exit of the nerves is seen.

af, anterior fissure; *n, n,* spinal nerves.

In the interval between each pair of nerves, we find a triangular process of fibrous membrane which is inserted by its apex into the dura mater. This process lies in the sub-arachnoid cavity and adheres by its base to the pia mater. It seems to pierce both layers of the arachnoid, or to pin them down, as it were, to the dura mater.

At the foramen magnum the spinal arachnoid may be seen to be continuous with that of the brain, and here its visceral layer invests the medulla oblongata loosely. Inferiorly we trace the membrane down quite to the lowest extremity of the dura mater, and in this region the visceral layer is particularly loose and free, as it lies over the cauda equina.

When the dura mater is carefully slit up along either the anterior or the posterior surface, the arachnoid sac is laid open. It does not always happen that the parietal layer separates very readily from the visceral: frequently the two layers adhere firmly at several minute points, yet this adhesion is effected without any connecting membrane, and appears to arise from the two layers becoming dried at several corresponding points, and thus being, as it were, glued together. We may frequently observe this in specimens that have been some time kept in spirits. This point is deserving of notice, as these adhesions might be (and indeed they have been) noted as of a morbid nature.

The visceral layer of the spinal arachnoid is connected to the pia mater by means of a number of long filaments of fibrous tissue which interlace slightly, and in the areolæ thus formed the fluid is contained. This tissue is most distinct and abundant in the cervical region, and exists in very small quantity in the dorsal. It ceases nearly altogether over the cauda equina. Numerous minute bloodvessels are also to be found in it passing from the pia mater to the arachnoid. Majendie gives to this tissue the name "*tissu cellulo-vasculaire sub-arachnoide.*"

In general the adhesion of the visceral layer of the arachnoid to the subjacent pia mater is closer along the posterior than along the anterior surface of the cord.

Along the posterior surface of the cord on the median line, the sub-arachnoid space is divided by means of a septum, which is most perfect in the dorsal region, but which in the lumbar and cervical regions is cribriform or pectiniform, as may be shown by pouring quicksilver on either side of it, which will be retained in the dorsal region, but will readily pass from right to left in the other situations. It is highly probable that this septum is a modified portion of the sub-arachnoid tissue.

The existence of this septum (erroneously described as complete) dividing the posterior part of the sub-arachnoid space into a right and a left portion, appears to have led to the opinion that this space is lined by another serous membrane, which has been called *the internal arachnoid,* by which the fluid is supposed to be secreted, and that the septum is formed by the reflection of its visceral into its parietal layer along the median plane. But there are many objections to this hypothesis. In the first place, if the septum were formed by the reflection of a serous membrane, it would be complete, and not a very imperfect one such as it is; it ought to resemble the mediastinum in the chest, or one of the processes of the peritoneum in the abdomen. Secondly, it is quite contrary to all experience to find the cavity of a serous membrane in the normal state traversed by a quantity of filamentous tissue, as the sub-arachnoid space is throughout a great part of its extent. Thirdly, were there a serous membrane in this space, the microscope ought to detect an epithelium on its inner surface, but such a structure does not exist here. Lastly, such a serous membrane must necessarily be continued into the encephalic sub-arachnoid space. But the close adhesion of the visceral layer of the arachnoid to the pia mater, opposite to the prominent parts of the cerebral convolutions, seems quite incompatible with such an arrangement.

Cerebral arachnoid.—The cerebral portion of the arachnoid exhibits essentially the same general arrangement as the spinal portion. Its parietal layer adheres very intimately to the pia mater at certain points, leaving in the intervals a considerable space for the accumulation of liquid. If we trace it over the surface of the hemispheres, it will be found to give them that smooth and uniform character which is always distinct on the recent healthy brain. The arachnoid passes from convolution to convolution, adhering closely to the pia mater over the most convex portions of those convolutions, but allowing that membrane to separate from it in the intervals between them, and to dip down to the bottom of the sulci. Hence liquid accumulated in the cerebral sub-arachnoid space will be found to take the direction of the intergyral sulci, and to cause the membrane to bulge opposite to them; and if air be blown underneath the arachnoid, it will be found to take the tortuous course of these sulci.

The arachnoid sinks into the great longitudinal fissure of the brain, lining the surfaces which bound it on each side, and passing across from right to left beneath the inferior margin of the falx, and above the corpus callosum.

On the base of the brain, the arachnoid has the same arrangement on those parts where there are convolutions, as on the superior and lateral surfaces of the hemispheres. It passes over the fissure of Sylvius from the anterior to the middle lobe, and here its distinctness from the pia mater may be clearly demonstrated; here too it appears much stronger and more opaque than elsewhere, which is probably due to the existence of an increased quantity of fibrous tissue beneath it.

In that space on the base of the brain which is bounded on each side by the middle lobes, and which is limited in front by the optic nerves and behind by the pons Varolii, the arachnoid membrane stretches across from one middle lobe to the other, leaving a considerable space between the tuber cinereum and the pons, in which it is connected to the pia mater by several long filaments similar to those which are met with on the surface of the spinal cord. This space is favourable for the accumulation of fluid, and it communicates in front with the fissures of Sylvius and other deep fissures into which fluid might make its way. Cruveilhier calls it the *anterior sub-arachnoid space*, and regards it as the principal reservoir of the cranial serosity. Immediately in front of it we observe that the arachnoid membrane is continued around the infundibulum to the pituitary body.

In tracing the arachnoid backwards from the great longitudinal fissure of the brain, we observe that it stretches down from the posterior edge of the corpus callosum to the superior surface of the cerebellum, crossing over the tubercula quadrigemina. At this situation the arachnoid is reflected upon the venæ magnæ Galeni as they pass to the straight sinus. It was at this place that Bichat described the canal which goes by his name, through which, as he thought, a process of the arachnoid membrane was carrried in to line the interior of the ventricles.

The arachnoid covers the superior surface of the cerebellum and also its inferior surface, stretching across the longitudinal fissure from one hemisphere to the other, and it is also extended downwards, and a little forwards from the superior surface of the cerebellum to the posterior surface of the medulla oblongata, below the inferior extremity of the fourth ventricle. A considerable space is thus left, situate posteriorly between the cerebellar hemispheres, and bounded in front and inferiorly by the medulla oblongata, which also forms a considerable reservoir for cerebral fluid, and communicates freely with the sub-arachnoid space of the spinal canal; but as the arachnoid is tied down somewhat more closely over the posterior surface of the spinal cord, there is an appearance of constriction where the cerebral passes into the spinal arachnoid. This space is called by Cruveilhier the *posterior sub-arachnoid space* (*posterior conflux* of Majendie). It communicates with the anterior sub-arachnoid space through the furrows around the crura cerebelli.

Of the cerebro-spinal fluid.—In examining such a dissection of the membranes of the spinal cord as that above described, we shall find that at various points the visceral layer of the arachnoid membrane appears raised up by fluid or by a bubble or two of air from the subjacent viscus. If a small portion of this layer be taken up in a forceps, and a blow-pipe be introduced into it, air may be blown underneath it, raising it up all around the spinal cord to a considerable distance from that organ. The inflation is more easily effected in the cervical and in the lumbar regions than in the dorsal, and the air will pass down quite to the lowest part of the canal of the dura mater, where the connexion of the arachnoid membrane to the cauda equina is particularly loose. In the same way coloured fluid, or some material which may assume the solid form, as size, tallow, &c. may be injected to demonstrate this anatomical arrangement. If now we examine a transverse section, it will be observed that a considerable interval exists between the visceral layer of the arachnoid and the pia mater of the cord, and that this interval is much greater in the neck and in the loins than in the back. We observe too that the spinal cord is by no means of sufficient size to fill the spinal canal, and that as a considerable interval exists between its surface and the visceral layer of the arachnoid, so also a still greater one is found between it and the inner surface of the dura mater. Now as it is of the very nature of a serous membrane that its free and smooth surfaces should always be in contact (for it is in that way that it favours the movements of the viscus with which it is connected), it is plain that the sub-arachnoid space in the spine must, during life, be kept in a state of distension, otherwise the object of a serous membrane would not be attained.

Moreover, in tracing the arachnoid membrane upwards over the medulla oblongata and the other parts of the encephalon, we observe an evident continuity between the spinal and the cranial sub-arachnoid cavity, which is most evident at the base of the brain, where the latter possesses the greatest dimensions, so that air or fluid may be readily made to pass from one to the other. This is most conspicuous in old subjects, in which the brain being small and more or less shrunken, leaves a considerable interval between its surface and the visceral layer of the arachnoid.

On opening the spinal canal in a body recently dead, the visceral layer of the arachnoid will almost always be found raised by fluid. When a portion of the posterior wall of the spinal canal is removed in a living animal, or in one just killed, the dura mater is found to be quite tense from the fluid which is accumulated within it. In a horse, whose spinal canal I opened in the dorsal region immediately after he had been knocked down in the knacker's yard, I found the dura mater perfectly tense, and semi-transparent from being stretched so firmly over fluid. Upon making a minute puncture in it, a fine stream of clear fluid was ejected with much force to a considerable distance, and immediately the dura mater became quite flaccid. By a little careful dissection through the dura mater and parietal layer of the arachnoid, it may be shewn that this fluid is not contained in the arachnoid sac, but in the sub-arachnoid cavity.

Sections of the spine in the lumbar region.

A, shews the section of the cord as well as of many roots of nerves descending to form the cauda equina.
B, shews the section of the cauda equina.
In both these regions the sub-arachnoid space is large and uninterrupted by bands or septa. The fluid permeates between and surrounds the roots of the nerves.

We can thus demonstrate the existence of a fluid, which during life and in a state of health occupies the sub-arachnoid cavity and maintains the two layers of the arachnoid membrane in contact with each other. This fluid is designated by Majendie the *cerebro-spinal* fluid.

The first distinct recognition of this fluid in its proper locality is due to Cotunnius, who stated the results of his observations in his memoir " de Ischiade Nervosâ," preserved in Sandifort's collection of dissertations. Cotunnius was led to the discovery by remarking the great disproportion between the dimensions of the spinal canal and the bulk of its contents, so that a considerable interval exists between the internal surface of the former and the spinal cord, which must be filled by something; and he attributes its having been so completely overlooked by previous anatomists to the fashion of opening the head before the spine, which favoured the escape of the fluid. This anatomist was also aware that the fluid was formed and contained in the sub-arachnoid cavity.

It is, however, to M. Majendie that we are chiefly indebted for our present knowledge of the physiological history of this fluid. Majendie's first researches were given to the public in his Journal de Physiologie for the year 1827, and he has lately collected the results of his inquiries in a volume entitled " Recherches Physiologiques et Cliniques sur le Liquide Cephalo-rachidien," and published in 1842.

The cerebro-spinal fluid is found wherever pia mater exists in connexion with brain or spinal cord, whether on the surface of these organs, or in the ventricles of the former. It serves to fill up various inequalities in the cranial or spinal walls, and it accumulates in greatest quantity in those situations where the sub-arachnoid space affords the greatest capacity.

Majendie describes four situations at which this fluid accumulates in greater quantity than at other places on the surface of the brain. The most considerable of these, which he designates the *posterior conflux*, is situated below and behind the cerebellum; it corresponds to the posterior surface of the medulla oblongata, and is covered behind by the layer of arachnoid which extends between the medulla and the cerebellum. (Vid. supr. p. 638.) It is here that, according to Majendie, a communication takes place between the fluid on the exterior and that in the ventricles, at a point corresponding to the inferior extremity of the fourth ventricle. A second, or *inferior conflux* is found immediately in front of the pons Varolii; it is situated between the crura cerebri, and contains the basilar artery. It is, in fact, only the posterior part of what Majendie designates the *anterior* conflux, which extends forwards to the commissure of the optic nerves, occupying the central depression between the middle lobes of opposite sides, and bathing in its fluid the commissure, the tuber cinereum, the infundibulum, and the trunks of the anterior cerebral arteries. It communicates with the posterior fissure beneath the crura cerebelli. The position and the extent of this conflux is indicated by the separation of the visceral layer of the arachnoid membrane over the central part of the base of the brain. Doubtless the accumulation of fluid around so many parts of important function and delicate structure, is a valuable safeguard to them against the communication of shocks from the walls of the cranium. A fourth conflux is called *superior;* it is situated behind and a little below the level of the corpus callosum, behind the pineal gland, and above the tubercula quadrigemina. It communicates around the crura cerebri with the anterior conflux, and with the posterior conflux by the fissures which separate the superior vermiform process from the hemispheres of the cerebellum. The fluid contained in it bathes the pineal gland, the tubercula quadrigemina, the superior vermiform process, and the *venæ Galeni* as they empty themselves into the strait sinus.

As the fluid is in contact with pia mater, it is plain that it must surround and support the roots of all the nerves which proceed from both the brain and spinal cord, and that all the bloodvessels which penetrate or emerge from those organs, or which ramify in the pia mater, must also be bathed by it. The fluid surrounds the nerves as they emerge from the cranium or spine, and maintains contact between the layers of arachnoid membrane which compose the sheaths that accompany them in their passage outwards. Majendie states that this fluid accompanies the roots of the fifth pair of nerves as far as the Gasserian ganglion, and that it bathes and mingles with the fibres of the ganglion itself, as well as of the three nerves which originate from it. This, however, I think extremely doubtful.

That fluid exists in the ventricles of the brain has long been known to anatomists; and it seems highly probable that this fluid is secreted by the processes of pia mater which are found in all these cavities; or possibly by the membrane which lines their surface. Does the internal fluid communicate with that in the sub-arachnoid space? Majendie affirms that a communication takes place by means of an opening which is situated at the inferior extremity of the fourth ventricle. I have not been able to satisfy myself of the existence of such an opening; the following is Majendie's description of it: "The true orifice, constant and normal, by which the cerebro-spinal fluid continually passes, either to enter the ventricles or to issue from them, may be seen at the inferior termination of the fourth ventricle, at the place named 'le bec de la plume' by the old anatomists.

"To demonstrate the existence of this orifice it is necessary to raise up, and to separate slightly from one another, the lobules of the inferior vermiform process of the cerebellum, and without breaking any of the vascular adhesions which unite this part of the cerebellum with the spinal pia mater, we perceive the angular excavation which terminates the fourth ventricle. Its surface is smooth, even *(polie)*, and is prolonged as far as the ventricle of the cerebellum. Such is the anterior part of the orifice: the lateral and superior parts are formed by the choroid plexuses of the organ and by a horny medullary lamella (valve of Tarin), the extent of which is variable, and which adheres to the prominent border of the fourth ventricle. The form and dimensions of the opening vary with the individual, and with the quantity of cerebro-spinal fluid, so that when the latter exists in considerable quantity the opening can admit the extremity of a finger. Most frequently, when the quantity of the liquid is normal, the orifice does not exceed two or three lines in diameter in every direction, but it is frequently subdivided by vessels which pass from the medulla oblongata to the cerebellum. Sometimes the orifice is restricted by one or by both of the posterior cerebellar arteries which pass across it."

Such is the description of the orifice to which Majendie has given the high-sounding title "*Orifice des cavités encephaliques*." He states that when fluid is injected into the spinal sub-arachnoid cavity, it makes its way into the ventricles of the brain through this orifice, a statement sufficiently difficult to prove. Cruveilhier, who seems to lean towards Majendie's opinion, admits nevertheless several weighty objections to it. The most important of these appears to me to be that the margins of the orifice which is brought into view by the method directed by Majendie, are irregular, and have the appearance of lacerated membrane. And it is recorded by M. Martin St. Ange, on the authority of Cruveilhier, that in fifteen subjects in which the latter anatomist found this orifice, its margins had the torn appearance in every one; "that around the opening, here and there, there existed the debris of membranes."*

My own opinion is that this orifice does not exist naturally, but that it is produced by the violence to which the brain is subject in its removal, or in the manipulations necessary for demonstrating it. It appears to me that the fourth ventricle is closed in the same way as the inferior horn of the lateral ventricles, namely, by the reflection of its proper membrane from its floor on to the adjacent pia mater. This membrane is so extremely delicate that the slightest traction upon it is sufficient to disturb its connexions. Its existence may be best proved by the resistance which a probe pushed into the fourth ventricle from above experiences at its inferior extremity, a resistance, however, which a little force can overcome. Or, if the fourth ventricle be opened from the side, by a vertical section of the median lobe of the cerebellum some distance to one side of the median plane, and if this be done on a brain previous to its removal from the body, or on one which has been removed with great caution, so as to occasion the least possible disturbance to the parts, it will be found that the ventricle is closed below by the reflection of its proper membrane upon the pia mater. There can be no doubt that fluid driven against this membrane with force would easily rupture it, whether from within the ventricle or from the sub-arachnoid space.†

It is plain that if there be a direct communication between the fluid in the ventricles and that in the sub-arachnoid cavity at the inferior extremity of the fourth ventricle, it must take place through an opening in that portion of the pia mater which ascends into the fourth ventricle to form the choroid plexus. But it is not necessary to have recourse to such a supposition to account for the transmissibility of fluid from one cavity to the other, for the pia mater is evidently hygrometric, and will readily admit of the passage of fluid through it by endosmose, and it is highly probable that, if any interchange of fluid takes place between the intra-ventricular cavity and the sub-arachnoid space, it is accomplished through the influence of endosmose and exosmose, effected not merely by the pia mater at the inferior extremity of the fourth ventricle, but likewise by that at the inferior cornua of the lateral ventricles, and perhaps also by that of the third ventricle, at the velum interpositum. And it is worthy of remark, as tending to confirm this opinion, (which, so far as I am aware, has not previously been suggested,) that at each of these situations there is a conflux (to use Majendie's phrase) of the sub-arachnoid fluid.

Cruveilhier lays some stress upon the fact that in apoplexy the blood escapes from the ventricle into the sub-arachnoid space. For my own part, I would say that this occurrence takes place as often, if not more frequently, at the inferior cornua of the lateral ventricles, as at the fourth ventricle. And therefore, if such a fact be used as an argument in favour of the direct communication of the latter with the sub-arachnoid space, it ought equally to lead to the supposition of the existence of similar orifices at the former situations, the absence of which may be easily proved. Moreover it may be stated that blood sometimes extravasates into the arachnoid sac, breaking through the arachnoid membrane; it is, therefore, less difficult to conceive its bursting the pia mater, which is evidently more porous, and is the seat of those vessels from which the hemorrhage comes, a morbid condition of which is the frequent precursor of the apoplectic attack.

The best way of obtaining the sub-arachnoid fluid with a view to form an estimate of its quantity, is to open the dura mater and arachnoid in the lumbar region of the spine, having previously, by means of a trephine, made a small perforation in the skull, so as to allow the pressure of the atmosphere to bear upon the cranial contents. "If," says Cotunnius, "you open the vertebræ of the loins before the head is touched, and cut the enclosed tube of the dura mater, a great quantity of water will burst out, and after all this spontaneous flux of water is spent, if you lift up the head, and shake it toward the aperture, a more plentiful stream will burst out, as if a new fountain was unlocked. In these experiments, which I made on the bodies of near twenty adults, and which I repeated at different times, I could draw off freely from the hollow of the spine four and sometimes even five ounces of water: I commonly found it very clear in such subjects, although it sometimes inclined a little to a yellow colour; but in fœtuses strangled in difficult labour, little as it was, I observed it to be always red and opaque."*

The estimate of the quantity of sub-arachnoid fluid here assigned by Cotunnius exceeds that which Majendie deduces from his experiments, who states that in general in a subject of adult age and mean size, and in moderate condition, two ounces may be regarded as the minimum quantity. Much depends upon the age and size of the subject and the state of nutrition of the nervous centres. In children the quantity is very small; in old age, when the brain and spinal cord have shrunk considerably, the quantity is large. In examining the bodies of the aged poor, as Majendie remarks, eight, ten, or twelve ounces of fluid may be obtained from the cranio-spinal cavity, according as there is a greater or less degree of atrophy of the brain.

In judging of the quantity of fluid around as well as within the cerebro-spinal centres,

* Martin St. Ange. Sur les membranes du cerveau et de la moelle epiniere.

† See the description of the fourth ventricle further on.

* From an English translation of Cotunnius's essay, entitled, A Treatise on the Nervous Sciatica, or Nervous Hip Gout, translated by Henry Crantz. London, 1775.

the time which has elapsed since death must be taken into account. As advancing decomposition favours the transudation of fluids through the tissues, it is plain that the longer this period is, the less liquid will be found; and the earlier after death the investigation takes place, the nearer will be the resemblance of the parts to their condition during life. On the other hand, a very advanced stage of decomposition will favour the developement of liquid, wherever space may be found for its accumulation. It is, therefore, in vain for the pathologist to attempt to form an opinion respecting the quantity of the fluid found in the cranio-spinal cavity, unless the inspection have been made at an early period after death.

Practical men are too much in the habit of attributing morbid phenomena of the nervous system to the influence of the pressure of a liquid effusion upon the brain or spinal cord. Many facts tend to shew that in a large proportion of cases, especially in the adult, the occurrence of an increased quantity of fluid, either around those centres or within the ventricles, is *a result*, and that it is probably a result *of a conservative kind*, consequent upon a morbid change which depresses the general nutrition of those organs themselves. We have seen how the universal decay of the tissues, which characterizes old age, favours the increase of the cranio-spinal liquid, when it affects the brain and spinal cord. In examining the bodies of habitual drunkards, patients who die of delirium tremens, or of cirrhose of the liver, the quantity of fluid is always found to be considerable and the brain shrunk. In bed-ridden persons who have ceased to exercise their faculties for some time, whether for mental or bodily exertion, the same phenomena are witnessed. When there has been much anæmia, as in cases where death has terminated a protracted illness, in phthisis for example, or in persons who have died of hæmorrhage, or after excessive venesection, the nervous centres will be found to be small and the liquid in large quantity. In extreme cases of lead cachexy, in which the nutrition of the nervous and muscular tissues is materially diminished, I have observed similar appearances. And, when any partial atrophy of either brain or spinal cord has occurred, there will invariably be found, at a point corresponding to it on the exterior of the organ, a local accumulation of fluid occupying a depression on its surface which has been caused by the giving way of the nervous substance within.

On the other hand an increase in the quantity of the nervous substance, or an enlargement of the brain or spinal cord, consequent on an undue injection of their bloodvessels, is invariably accompanied with a diminution in the quantity of this fluid or with the total absence of it. In hypertrophy of the brain no fluid is found in the subarachnoid space, and very little or none in the ventricles. In cases of tumour of the brain encroaching upon the cranial cavity, we find no fluid; and the same is observed where chronic inflammation of the brain has given rise to a new deposit which increases the bulk and the density of the cranial contents. In all cases where a considerable quantity of fluid has accumulated *within* the ventricles, that upon the surface is either greatly diminished or entirely disappears. In the ordinary hydrocephalus internus of children fluid is never found on the exterior of the brain.

When an arrest in the developement of any portion of the cerebro-spinal axis has taken place, the space which ought to be occupied by the organ of imperfect growth is filled by liquid. In examining the heads of idiots we always find a considerable quantity of subarachnoid fluid, either general, or partial if a portion only of the brain be deficient. Or if any portion of the wall of the cranio-spinal cavity be defective, the contained viscus is protected by the accumulation of an increased quantity of liquid in the situation of the deficiency. Hence the explanation of those watery tumours which occur over various regions of the spine, in cases of *spina bifida*, in which the accumulation of water is favoured by the absence of the resisting osseous wall of the spine for a greater or less extent. And similar tumours are found projecting from the cranium, being occasioned by a protrusion of the cranial meninges through a congenital aperture, containing fluid and sometimes a portion of the encephalon itself.

Enough has been said to show, that the preternatural increase of this fluid should in general be regarded as secondary to and consequent upon the diminished size of the cerebro-spinal centre itself, and that it has most probably little or nothing to do with the manifestation of peculiar symptoms during life in the great majority of instances. Whatever be the immediate cause of the shrinking of the cerebro-spinal centre or of any portion of it, the increase of the fluid goes on *pari passu*, and in a quantity duly proportionate to the decrease of its bulk, so that it is in the highest degree improbable that, in such cases as I have enumerated, the nervous centre experiences any increased degree of pressure beyond that which it bears in the normal state. If, however, the fluid, either within or without the brain, were to increase, while that organ itself either preserved the same bulk or became enlarged, it is plain that it must experience an increased degree of compression, which doubtless would produce serious symptoms. This very rarely happens, according to my experience, as regards the subarachnoid fluid on the exterior of the brain: we more frequently meet with an increase of the fluid within the ventricles, and, in such cases, we shall find evidence of the compression in a manifestly greater firmness and density of its structure, and in this fact, that the lateral ventricles, when laid open by a horizontal section, do not collapse, as in the ordinary state of the brain, but remain quite patulous, owing to the firmness and density of their walls. And this patulous state of the ventricles may be regarded as a good indication that the fluid, collected in them, had for some time occasioned a preternatural amount of pressure.*

Majendie infers, and as it appears to me with justice, that the cerebro-spinal fluid is secreted from the vessels of the pia mater. He states that, when a portion of the pia mater is exposed in a living animal, "an attentive eye may observe the transpiration of a liquid which evaporates, it is true, almost as soon as it appears, but which is sufficient to prevent the drying of the membrane." "To render this phenomenon of vital physics still more manifest," he adds, "it is necessary to inject a certain quantity of water, at 30° R., into the veins of the animal which is subjected to the experiment; immediately the liquid exhalation of the pia mater takes place in a more rapid manner, and consequently becomes more apparent." We ought to be content with M. Majendie's statement respecting this experiment: the point in question is by no means of sufficient consequence to warrant the repetition of so cruel an experiment.

Majendie's experiments have demonstrated further that this fluid can be as quickly regenerated as the aqueous humour of the eye. He found that on puncturing the theca of the spinal cord, and perforating both layers of arachnoid membrane, the fluid quickly escapes at first as a fine continuous jet, and afterwards *per saltum* in correspondence with the efforts of expiration. If the orifice be closed up and the animal left to go at large for twenty-four hours, the fluid is reproduced in as considerable quantity as before the first experiment.

What has been described as the movement of this liquid consists in an alternate elevation and collapse synchronous with expiration and inspiration, seen only when a portion of the cranio-spinal wall has been removed, and caused by the repletion of the venous system of the spine which occurs in the former state of the respiratory movements, and its collapse which takes place in the latter. The distended spinal veins compress the cerebro-spinal fluid, and cause it to rise towards the head in expiration; their collapse in inspiration favours the movement of the fluid in the contrary direction. We have no evidence from experiment or direct observation that there is any movement in the fluid of the ventricles; but the discovery of cilia upon the inner surface of these cavities seems to indicate that this fluid is not quite stationary within them.

The following account of the physical and chemical properties of the cerebro-spinal fluid is derived from Majendie's researches. When removed from the body a few moments after death, this fluid is remarkably limpid, and may be compared in this respect to the aqueous humour of the eye; sometimes it has a slightly yellowish tinge. In temperature it ranks among the hottest parts of the body. It has a sickly odour and a saltish taste; it is alkaline, restoring the blue colour of reddened litmus.

* See an important paper by the late Dr. Sims on serous effusion in the brain, Med. Chir. Trans. vol. xix.

Lassaigne's analysis of the human fluid yielded the following result.

Water	98.564
Albumen	0.088
Osmazome	0.474
Hydrochlorate of soda and of potass	0.801
Animal matter and phosphate of soda	0.036
Carbonate of soda and phosphate of lime	0.017
	99.980

According to M. Couerbe, some of the secondary organic products which he has obtained from the brain are to be found in this fluid. The following constituents are enumerated by this chemist: 1. an animal matter insoluble in alcohol and ether, but soluble in alkalis; 2. albumen; 3. cholesterine; 4. cerebrote; 5. chloride of sodium; 6. phosphate of lime; 7. salts of potass; 8. salts of magnesia.

What is the use of the cerebro-spinal fluid? An obvious mechanical use of this fluid is to protect the nervous centres with which it lies in immediate contact. By the interposition of a liquid medium between the nervous mass and the wall of the cavity in which it is placed, provision is made against a too ready conduction of vibrations from the one to the other. Were these centres surrounded by material of one kind only, the slightest vibrations or shocks would be continually felt, but when different materials on different planes are used, the surest means are provided to favour the dispersion of such vibrations.

The nervous mass floats in the midst of this fluid, being maintained in equilibrio in it by its uniform pressure on all sides, and the spinal cord, as we shall find by-and-bye, is supported by an additional mechanism which prevents its lateral displacement.

By its accumulation at the base of the brain, this fluid must protect the larger vessels and the nerves situate there from the unequal pressure of neighbouring parts.

It is not improbable also that this fluid may contribute to the nutrition of the brain and spinal cord, by holding in solution their proper nutrient elements preparatory to their absorption or addition to the nervous masses themselves; and this view would receive great support if Couerbe's analysis, which detects some of these elementary matters in the fluid, should be confirmed by the observations of other chemists. Nor must we omit to notice here, the fact ascertained by Majendie, that when certain substances which find their way readily into the blood have been injected into the veins, they may be soon after detected in this fluid, such as iodide of potassium.

Majendie observed serious symptoms to ensue upon the removal of this fluid from living dogs, but it is impossible to ascribe such symptoms solely to this cause, for the introduction of air into the subarachnoid cavity, the disturbance and consequent irritation to which the nervous centres must necessarily be exposed in the performance of the experiment, ought fairly to be considered to have a share, and that not an inconsiderable one, in any impairment of the nervous function that might become apparent. The sudden removal of the fluid brings on fainting or even death, effects due to shock, and analogous to those which result from the sudden removal of dropsical fluid in particular cavities, when the organs and the circulation in them have become adapted to its pressure, as in cases of ascites, hydrothorax, &c.

The interior of the arachnoid sac is moistened by an exhalation of a similar kind to that which is found in the other serous membranes. Accumulations of fluid in the arachnoid sac, however, are of very rare occurrence.

Of the glandulæ Pacchioni.—To these bodies we have already had occasion to refer in the description of the sinuses. We proceed now with a more special notice of them.

These bodies were first formally described by Pacchioni, and were regarded by him as conglobate glands of the dura mater, from which lymphatics proceeded to the pia mater.* They have been recognized by all subsequent anatomists under the name here assigned to them, although the idea of their physiological office suggested by Pacchioni has not met with general acceptation. Bichat suggested a more appropriate and scientific appellation in that of *cerebral granulations*. No anatomists have investigated the history of these bodies so extensively as the brothers Wenzel.†

The Pacchionian bodies are found principally along the edge of the great hemispheres of the brain on either side of the great longitudinal fissure. Here, in general, they cause the obliteration of the sac of the arachnoid for a greater or less distance by producing adhesion between the visceral layer of that membrane and that portion of its parietal layer which adheres to the angle along the superior border of the falx cerebri. In cases where these bodies are numerous and well developed, it is found very difficult to separate the dura mater from the subjacent arachnoid by reason of the firmness of the adhesion effected by them; and when this adhesion exists, the corresponding surface of the dura mater has generally a very complicated cribriform appearance. The extent of surface which they occupy is very variable. Sometimes, but very rarely, they extend along the entire edge of each cerebral hemisphere; but generally they occupy its central part for an extent of from one to three inches. Very frequently they extend outwards over the surface of the cerebral hemispheres, rarely beyond half an inch or an inch. The arachnoid membrane in their immediate vicinity is always opaque.

Bodies, somewhat similar, are also found occasionally on the choroid plexuses of the lateral ventricles. Very frequently we meet with granulations of a like kind in the fringe-like process of pia mater which descends from the velum interpositum to surround the pineal gland, and also upon the little processes of that membrane which go under the name of choroid plexuses of the fourth ventricle.

Wherever these bodies are found, they show a remarkable tendency to congregate in clusters around venous trunks. In examining them along the edges of the hemispheres, we find that they are most numerous around the veins which pass from the pia mater in that situation into the superior longitudinal sinus. This tendency, probably, explains the occurrence of these bodies in some of the sinuses. They are most commonly met with in the superior longitudinal sinus, as already stated; they are also found in the lateral sinuses, and sometimes but rarely in the straight sinus. In all these situations these bodies appear to stand in a similar relation to the sinuses; they have penetrated the fibrous tunic of their walls, and pushed before them the inner or venous tunic.

In point of size and shape the Pacchionian bodies resemble minute granulations; their colour is white, like that of coagulable lymph, and not unlike that which is occasionally seen upon serous surfaces after chronic inflammation. A granular lymph, taking somewhat a similar form, is occasionally seen on the mucous membrane of the rectum after dysentery. At some parts the granulations appear simply as isolated elevations of the surface of the arachnoid membrane. At others they are collected in clusters round a common stem; and when the membrane is removed and floated in water, this bothryoidal disposition may be well displayed. A large proportion of them cause, by their pressure, an adhesion between the opposed surfaces of arachnoid membrane; and those which are attached to a stem are the most likely to project into the interior of the sinuses.

When examined by a microscope, each of these bodies appears to consist of a mass of minute granules enclosed in a membranous sac; when the body is pediculated, its stalk exhibits a series of striæ which take the direction of its length, and probably result from longitudinal folds of the membrane which forms it. Dilute acetic acid causes them to swell and gelatinifies the bodies, and sometimes displays epithelial scales upon the surface of the membrane which covers them.

The following explanation of this structure may be offered. The primary deposit of granular lymph takes place among the vessels of the pia mater. The small bodies thus formed push the arachnoid membrane before them as a sac or covering; in some instances the granular mass is only partially covered, and then it causes merely a slight projection on the surface of the visceral layer of arachnoid; but in others the mass is completely covered, and a stalk is gradually formed; and when several granular masses have been deposited immediately contiguous to each other, they may all

* Ant. Pacchioni diss. epistolaris ad Luc. Schroeckhium de glandulis conglobatis duræ meningis humanæ, &c. &c. Rom. 1705, et Opusculum Anatomicum de durâ meninge, in Opera Omnia. Rom. 1741.

† Wenzel, de penitiori cerebri structura. Tubingæ, 1812.

be attached in a cluster to the same stem. The fact that epithelial particles may be seen upon the surface of the membranous sac of some of the bodies is sufficient proof that it is derived from arachnoid membrane. If this be admitted, then it seems impossible to come to any other conclusion than that the pia mater is the seat of the primary deposit, and this opinion is confirmed by the fact that we meet with the Pacchionian bodies on the internal processes of the pia mater, when we have no evidence of the existence of arachnoid membrane.

Or it might be conjectured that these bodies indicate a degenerate condition of the elementary particles of the superficial layer of the grey matter of certain convolutions, produced by frequent irritation.

Are the Pacchionian bodies natural structures? The great frequency with which these bodies are met with in the various situations abovementioned, has induced many, even in the present day, to regard them as normal structures, the physiological office of which is as yet unknown. But there are many facts which strongly militate against such a conclusion. In the first place it may be observed that Pacchionian bodies never occur in the earliest periods of life. In the course of a long experience in anatomical investigations I have never seen them at a period antecedent to six years. The brothers Wenzel, who made a series of special examinations with a view to determine this question, make the following statement. In children, from birth to the third year, these bodies, if they ever occur, must be very few. From the seventh to the twentieth year they sometimes are numerous. From the latter period to the fortieth year their number is considerable, and the nearer we approach the fortieth year the greater does it become. Lastly, from the fortieth to the one hundredth year these bodies are found in great numbers.

It must be further remarked that even at those periods of life when the Pacchionian bodies are found in greatest numbers, cases frequently occur in which no trace of them can be found. There is likewise the greatest variety as to their number and size, in different individuals of the same age.

It has always occurred to me to find them most numerous in cases where I had reason to know that the brain had been subject to frequent excitement during life. In persons addicted to the excessive use of spirituous liquors, in those of irritable temperament and who were frequently a prey to violent and exciting passions, they are almost uniformly highly developed.

The Pacchionian bodies are peculiar to the human subject. Nothing similar to them has been found in any of the inferior classes of animals.

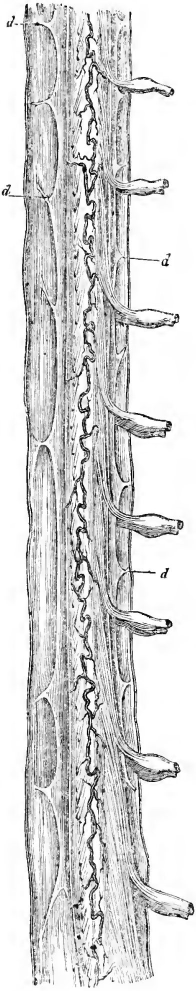
In reference, then, to the question, what is the nature of these bodies, I have no difficulty in stating my opinion that the evidence greatly preponderates in favour of their morbid origin; that they are the product of a chronic very gradual irritation due to more or less frequent functional excitement of the brain itself. It is not unlikely that the friction to which the opposed surfaces of the arachnoid are continually subjected in the movements of the brain, especially when they are of a more rapid and violent kind, as under states of cerebral excitement, may contribute to the developement of many of the appearances connected with these bodies. The opaque spots which are of such frequent occurrence upon the surface of the heart may be quoted as an example of a morbid change, very commonly met with, and resulting probably from the friction against each other of opposed serous surfaces. Were the Pacchionian bodies normal structures, they would not be so frequently absent from brains which afforded every other indication of being in a healthy state; nor should we find opacity of the arachnoid (a decidedly unhealthy condition) so commonly coexistent with the full developement of them. Again, were they a necessary part of the healthy organism, we might expect to find them more constant as regards size, number, and the extent of surface over which they were placed.

Of the ligamentum dentatum (serrated membrane of Gordon).—This structure forms a part of the mechanical arrangements connected with the spinal cord and the roots of its nerves. It is found in the subarachnoid space, adhering on the one hand to the pia mater, and, on the other, attached at certain intervals to the dura mater.

The ligamentum dentatum consists of a narrow longitudinal band, adhering by its inner straight border to the pia mater on each lateral surface of the spinal cord, midway between the anterior and posterior roots of the spinal nerves, reaching from the highest point in the cervical region down to the filiform prolongation with which it becomes incorporated. Its outer border exhibits a series of tooth-like triangular processes which are inserted by their apices into the dura mater. The first pointed process, which is longer than the rest and less triangular in shape, is inserted into the dura mater on the margin of the occipital bone, where it stands in relation with some parts of interest. The posterior root of the sub-occipital nerve, and the filaments of origin and the resultant trunk of the spinal accessory, are on a plane posterior to it. The vertebral artery and the ninth pair of nerves are anterior to it. The number of teeth varies from eighteen to twenty-two. The last is attached to the dura mater about the level of the first or second lumbar vertebra. The points of attachment are between the points of exit of the spinal nerves, being almost always nearer the lower than the upper nerve. The intervals between each pair of dentated processes vary in different regions of the spine as the distances between the roots of the nerves vary. At its insertion into the dura mater each process pins down the visceral and parietal layers of the arachnoid membrane, probably piercing them to reach the fibrous membrane. At its lowest part, a little above the extremity of the cord, the denticulated margin ceases, and the longitudinal portion may be traced downwards, gradually diminishing in size, along each side of the filiform prolongation of the pia mater.

The dentated ligament has to the naked eye

Fig. 370.



Dura mater of part of the spinal cord laid open to show the ligamentum dentatum.

d d d d, dentated processes. On the right the roots of the nerves and the ganglia of the posterior roots are retained.

all the characters of white fibrous tissue, of which it is chiefly composed. In its dentated processes, however, a considerable quantity of yellow fibrous tissue may be found. The similarity of its constitution with that of the pia mater evidently justifies its being regarded as a process of that membrane, and not, as some anatomists thought, of the dura mater, with which it has a much less intimate and extensive connexion. Its anterior and posterior surfaces are uncovered by any membrane; they are smooth, and have the glistening silvery appearance of white fibrous membrane. It is evident that during life these surfaces must be bathed by the subarachnoid fluid.

The office of this remarkable structure seems evidently to be mechanical; to preserve the spinal cord in a state of equilibrium; and to prevent lateral movement of it, whilst at the same time it forms a partition between the roots of the nerves.

General remarks on the structure of the nervous centres.—It has already been shewn in a former part of this article that the nerves properly so called are composed exclusively of one kind of nervous substance,—namely, the fibrous nervous matter, which is disposed in bundles of peculiar fibres. It is only in the nervous centres or in continuations of them that we find an union of the white and the grey nervous matter; and, indeed, it may be stated in general, that the peculiar and distinctive anatomical character of a nervous centre consists in this combination of the two kinds of nervous matter.

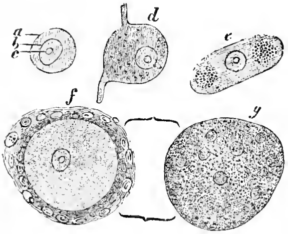
In the nervous centres the white matter exhibits, for the most part, the same essential characters of structure as in the nerves; that is to say, it is disposed in tubes containing a certain pulpy matter in them. It has been found, however, that these tubes are much more prone to become varicose under the influence of pressure or of any other disturbing cause. They are not, as in the nerves, bound together by areolar tissue, but are disposed in bundles and on different planes, with their nutrient bloodvessels ramifying among them, and in some situations the elements of the grey matter are interposed between them. Certain parts of the nervous centres are composed exclusively of white matter, as a portion of the hemispheres of the brain, and of the cerebellum, and the superficial parts of the spinal cord.

The white fibres which are found in the nervous centres may be distinguished according to their physiological office into four different kinds. Two of these are continuations of the fibres of the nerves, and serve to connect the nervous centres with other organs or textures, either by conveying the influence of the centres to them, or by propagating impressions from them to the centres. The former are called *efferent*, the latter *afferent* fibres. In addition to these, we find a third and large series of fibres, which serve to establish a connection between different centres, or between different portions of the same centre. These are called *commissural* fibres; they form a large portion of the mass of the brain and spinal cord. And Henle suggests that the brain contains a fourth series of fibres, associated with the operations of thought.

We remark in the nervous centres, especially in the brain and spinal cord, a greater difference as regards size between the different nerve tubes, than may be observed elsewhere, and it seems to be a constant character that they diminish in size as they approach and enter the grey matter.

Of the grey nervous matter.—The grey nervous matter differs very materially in its anatomical characters from the white. Its elements are vesicles or cells, with nuclei and nucleoli. Although this vesicular or cell form is universally prevalent, the cells present much diversity of shape, size, and colour in different centres or even in the same centre, which apparently have reference to some peculiarity of function. The most prevalent form is that of a globular vesicle, composed of a very delicate transparent membrane. Within this membrane is contained a soft minutely granular substance, which forms the principal mass of the body, *parenchymmasse* (Valentin). The grey colour of the vesicle, which becomes very manifest when a number of them is congregated together, is dependent on this granular matter. (See *fig.* 371, *a*, *b*, *c*.) When the vesicle bursts and its substance is broken up, the granular matter is diffused, and confuses and darkens the specimen under examination. Sometimes the outer vesicle is removed, the contained granular matter retaining the globular form. Within the external vesicle (*a*, *fig.* 371) there

Fig. 371.*



Nerve vesicles from the Gasserian ganglion of the human subject.

a, a globular vesicle with defined border; *b*, its nucleus; *c*, its nucleolus; *d*, caudate vesicle; *e*, elongated vesicle with two groups of pigment particles; *f*, vesicle surrounded by its sheath or capsule of nucleated particles; *g*, the same, the sheath only being in focus.

is another much smaller and adherent to a part of its wall, so as to be quite out of the centre of the containing vesicle. This is the *nucleus* (*b*, *fig.* 371). Its structure is apparently of the same nature as that of the external vesicle. The nucleus contains in its centre another minute and remarkably clear and brilliant body, also vesicular in structure. This is the *nucleolus* (*c*, *fig.* 371). Sometimes it is replaced by two or three much smaller but similar bodies. The softness of the vesicle admits of its yielding, whether from the disturbance occasioned in the necessary manipulation or from the pressure of the neighbouring elementary parts as it lies in its proper situation. Hence it is that these vesicles exhibit a considerable diversity of form.

* I am indebted to the accurate pencil of my friend Mr. Bowman for this illustration.

Very frequently we observe that, besides the granular substance above described, there are certain pigment particles of large size and dark colour, which are collected into one or two roundish or oval groups, situate at or towards one or both sides of the vesicle (*fig.* 371, *e*). These masses of colouring matter sometimes occupy considerable space, and enable the observer readily to detect the position of such vesicles as contain them. When the mass of pigment is placed at one side, we may compare the containing vesicle, as Volckmann has done, to a fruit which is coloured only on that side which is exposed to the sun. The aggregation of many such vesicles at any one spot gives the nervous matter there a peculiarly dark colour. A remarkable example of this is found in that portion of the crus cerebri which is known by the name of *locus niger*.

A very interesting form of nerve-vesicle is that which exhibits the greatest departure from the globular shape by the prolongation of the wall of the outer cell into one or more tail-like processes. These bodies may, from this peculiar character, be designated *caudate nerve-vesicles*. They possess the nucleus and nucleolus, as in the more simple form, and contain one or more of the masses of colouring matter; indeed, in them the quantity of pigment is generally much more considerable than in any other form. I have noted an observation which shewed two nuclei in one vesicle. They vary much in size and shape, and so also do the processes. The largest nerve-vesicles are found among those of this description. The variety in shape may depend in some degree upon the situations from which the caudate processes take their rise. In some (*fig.* 371, *d*) they proceed from opposite poles of the vesicles; in others they arise near each other from the same region of the vesicle, and when numerous, give to it somewhat the form of a cuttle-fish with extended tentacles. In examining the structure of one of these processes, we find it evidently exactly similar to that of the matter contained in the outer vesicle, exhibiting the same minutely granular appearance. The processes are implanted in the surrounding substance, and firmly connected with it, so as to be with great difficulty separated from it. They exhibit much strength of cohesion, but are frequently broken off quite close to their points of origin, and the broken ends present a distinctly lacerated edge (*d*, *fig.* 371). More rarely we are able to trace these processes to a considerable distance, and then we observe them to bifurcate or even to subdivide further, and to terminate in exceedingly fine transparent fibres, the connexion of which with the other elements of the nervous matter has not yet been ascertained.*

* See a beautiful illustration of one of the largest of these vesicles in the second part of Mr. Bowman's and my work on Physiological Anatomy and Physiology.

It is in vain, in the present state of our knowledge, to speculate upon the use of these caudate processes. Do they constitute a bond of union between the nerve-vesicles and certain nerve-tubes? or are they commissural fibres serving to connect the grey substance of different portions of the nervous centres? Until a more extended research has made us better acquainted with the peculiarities of these vesicles in various localities, it would be premature to offer any conjecture concerning their precise relation to the other elements of the nervous centres. They exist, with different degrees of developement, in the locus niger of the crus cerebri, in the laminæ of the cerebellum, in the grey matter of the spinal cord and medulla oblongata, and in the ganglions, and in the grey substance of the cerebral convolutions, in which latter situation they are generally of small size.

When a portion of grey matter from a convolution of the brain is examined with a high power in the microscope, we observe it to consist chiefly of a mass of granular matter, in which nerve-vesicles are imbedded with considerable intervals between them. Henle states, with much truth, that the superficial part of the grey matter of the convolutions seems almost entirely composed of finely granular substance, in which lie, scattered here and there, several clear vesicles which, as he remarks, look almost like openings (*fig.* 372). In the middle portion the vesicles appear larger, and the granular matter becomes less abundant, and on the most deep-seated plane the nerve-vesicles are much increased in size and lie in closer juxtaposition, being, however, covered by a thin layer of granular matter, which forms a sheath to each vesicle. Nerve-tubes are found throughout the whole depth of the grey matter. Those in the most superficial layer are extremely fine and varicose, and seem to correspond in number and situation to the vesicles. For wherever there is a nerve-vesicle, we find an extremely fine varicose nerve-tube apparently adherent to it.

Fig. 372.

a, nerve-vesicle; *b*, a similar one with two nuclei; *c*, another viewed along its edge; *d*, vesicles indistinctly apparent; *e*, granular matter.

In the grey matter of the ganglions we find that the vesicles are also deposited in granular matter, which surrounds each of them as a sheath (*fig.* 371, *f*, *g*), completely investing it on every side, and separating it from the neighbouring ones. Here, however, the sheath is formed not only of a finely granular matter, but also of numerous bodies which resemble nuclei or cytoblasts, and this sheath invests both the globular variety of nerve-vesicles and the caudate ones. Nerve-tubes lie in immediate connexion with these vesicles, and sometimes entwine themselves around them, and seem to indent their sheaths (*fig.* 375.)

Other vesicles, much more simple in form, are found in the grey matter in certain situations. The outer layer of the optic thalamus, according to Henle, contains only small homogeneous globules, analogous to the nuclei of the ganglionic globules, in immediate apposition with each other, and towards which the tubes seem to ascend in the vertical direction. Purkinje states, that a similar layer is met with in the cortical substance of the brain quite close to the medullary substance.* I find a layer of similar particles in the grey matter of the cerebellic laminæ. And, according to the report of Valentin,† Purkinje has found the interior of the ventricles in the normal state covered by an oily matter, which consists of distinct, large, transparent globules, free and lying near each other. A similar layer has been found by him in the interior of the fifth ventricle. The cavity of the rhomboidal sinus in Birds likewise contains a gelatinous mass, which consists of large globules lying close to each other.‡

Developement of grey matter.—In the perfect nerve-vesicle, the cell form of primitive developement is persistent. We have the nucleolus and nucleus (cytoblast) and the cell; and, according to Schwann, the only change which the full-grown cell exhibits consists in an increase of size and in the developement of the pigmentary granules within. The following is Valentin's description of the developement of a nerve-vesicle. In the very young embryos of Mammalia, as the sheep or calf, the cerebral mass in the course of formation contains, in the midst of a liquid and transparent blastema, transparent cells, with a reddish yellow nucleus. The wall of the cells is very thin and simple; their contents are colourless, transparent, homogeneous, and manifestly liquid; the nucleus, with well-defined contour, is generally round, sometimes central, at other times excentric, solid, and nearly of the same colour as the corpuscles of the blood. Around these primitive cells of the central nervous system, which we find likewise formed after the same type in the spinal cord, a finely granular mass becomes deposited, which probably is not at first surrounded by an enveloping cell-membrane. At this early period of formation the primitive cell still preserves its first delicacy to such a degree that the action of water causes it to burst immediately. This rupture of its membrane and effusion of its contents often take place so suddenly and quickly that they can be perceived

* Henle, loc. cit. † Uber den Verlauf, &c.

‡ See further remarks on the grey matter in the account of the minute structure of the brain and spinal cord in a subsequent part of the article.

only by the movement of the nucleus, which is the consequence of it. * * * In proportion as the granular mass contracts itself within certain limits, (sich immer mehr abgrenzt,) a cell-membrane probably becomes developed around it, so that the vesicle gradually acquires its precise form and size, and its contents their proper characters, which belong to a fully formed central nervous corpuscule.* Valentin compares the developement of these vesicles to that of the ovum. The nucleolus of the nerve-vesicle is always first formed, then around it the primitive cell, and around this the outer cell. This process resembles exactly that which takes place during the formation of the ovum, for the germ corresponds to the nucleolus, the germinal vesicle to the nucleus, the yolk to the contents of the outer enveloping cell, and the vitelline membrane to the delicate wall of this cell, supposing that this latter membrane always exists.†

The great simplicity in the form of the elements of the grey nervous matter is one of its most remarkable characteristics. That a tissue, which, as will be shown by-and-bye, plays so prominent a part in the nervous actions, whether they are prompted by mental change, or are purely corporeal, should exhibit scarcely any more complexity of structure than that which is found in the simplest animal or vegetable textures, or in structures that have not passed their earliest phase of developement, is an anatomical fact pregnant with great physiological interest. Have this simplicity of form and delicacy of structure reference to the celerity of the nervous actions? or to that proneness to change which must be induced by the constant and unceasing round of impressions which the grey matter must receive from the ordinary nutrient actions that are going on in the body, as well as from the continual action of thought? If, according to common acceptation, we admit that the mind is in immediate connexion with the cerebral convolutions, it may well be imagined that no part of the frame can be the seat of such active change, from its being on the one hand the recipient of impressions from the body, and, on the other, from an association with the psychical principle so intimate that probably, under ordinary circumstances, an affection of the one cannot occur without being communicated to and producing a change in the other.

Another curious fact, in connexion with the intimate structure of the grey nervous matter, is the large quantity of pigment or colouring matter which exists in it, and which appears to form one of its essential constituents, more abundant in some situations than in others, but present in all. We are utterly ignorant of the design of this peculiarity of structure. If this pigment bear any resemblance of chemical composition to the colouring matter of the blood, *hæmatosine*,—and it is not improbable that it does,—an increased interest attaches to the practical importance of minute attention, on the part of practitioners, to avail themselves of all the means which are capable of improving that important element of the nutrient fluid both in quantity and quality, for it is most reasonable to presume that the pigment of the nervous matter would derive its nourishment from that of the blood.

It may be further remarked that pigment occurs in connexion with the nervous system in another form besides that of incorporation with its elementary particles, that is, upon the exterior of parts of the nervous centres or of particular nerves. Examples of this may be referred to in the case of the olfactory nerve of the sheep and of other Mammalia, the bulb of which is surrounded by black pigment connected with the pia mater. It is also found sometimes on the pia mater of the spinal cord of the human subject. Valentin, who delineates a magnified view of this pigment, states that it occurs chiefly in the cervical region. In frogs, the whole spinal cord and encephalon are covered with a silvery pigment interspersed with black. The same occurs in fishes. The black pigment in connexion with the retina has an obvious use. On the choroid gland of fishes, which lies immediately contiguous to the retina and surrounds the optic nerve, there is a silvery membrane which contains a quantity of the same kind of pigment as that alluded to upon their nervous centres. On some of the ganglia of the invertebrata particles of pigment are likewise found.

Of the structure of ganglions.—The description of the minute anatomy of ganglions as well as of all other nervous centres may be regarded as the solution of the following problem: to determine the relation which the white substance of these centres bears to the grey matter on the one hand, and to the nervous trunks connected with them on the other hand.

The white substance of the ganglions consists of a series of minute nerve-tubes, as well as of some gelatinous fibres, which are continuous with those which exist in the nerves themselves. If we trace a nerve into a ganglion, it is found to break up into its component nerve-tubes, and it does so by a separation of the tubules within into smaller bundles, or single tubes. Sometimes adjoining bundles interlace, each yielding to its neighbour one or more tubes. The nerves which emerge from the ganglia derive their component nerve-tubes from different bundles, so that the same kind of interchange of tubules, which we have noticed as taking place in plexuses, occurs also in ganglia. The emerging nerves result from a further subdivision and greater intermixture of the bundles of nerve-tubes which enter the ganglions. The arrangement is well shown in *fig.* 373, where the nerve (*a*), which enters the ganglion, may be seen breaking up into a plexus, from which three branches (*b*, *b*, *b*) emerge, and it may be observed that these emerging nerves derive nerve-tubes from very different and opposite parts of the ganglionic plexus. In the meshes, which are left between the interlacing nerve-tubes, the ganglionic globules or nerve-vesicles are situate (*figs.* 373, 374). Certain fibres, according to Valen-

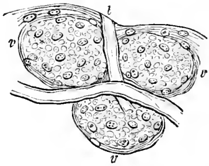
(After Valentin.)

tin, travel round the margin of the ganglion, and to these he gives the name of *umspinnende Fasern*, surrounding fibres, and some fibres pass from them to the more central ones, or from the latter to the former. Nerve-vesicles exist at the circumference of the ganglion as well as in its interior, and to them is due the peculiar grey colour of that body.

The best mode of examining these points is to select the smallest ganglia of very small animals, birds, mice, &c.; these, when subjected to compression, become very transparent, and display much of their intrinsic arrangement. Or thin slices of large ganglia may be placed under the microscope, and when torn up by needles the disposition of the nerve-vesicles and the caudate processes, when present, are rendered visible. And none is more suitable for this purpose than the Casserian ganglion of the fifth nerve, which by the absence of a dense sheath and its greater looseness of texture is more easily examined.

It is a highly important problem, in minute anatomy, to determine whether there are any nerve-tubes which terminate in the grey matter of the ganglion, or originate in it,—which in short are not continued through the ganglion. At present we are unable to state further than that the tubes appear to have an intimate connection with the nerve-vesicles wherever the latter may be found, and that they often appear to be continuous with the sheaths of the nerve-vesicles.

Fig. 375.



Nerve vesicles from the Gasserian ganglion covered by their sheaths of nucleated particles, to shew the intimate relation of the nerve-tubes to them.

t, t, nerve-tubes; *v, v*, vesicles.

There does not appear to be any material difference of structure between the ganglions of the sympathetic and those of the cerebro-spinal system, excepting, as Henle states, the existence of a greater number of gelatinous fibres in the former.

Of the cerebro-spinal centre.—The nervous mass which occupies the cavities of the cranium and spine doubtless constitutes one great centre, as there is a perfect continuity throughout all its parts. But the differences of external form and characters in some regions of it, and the obvious diversity of endowment of the nerves connected with certain portions, denote and justify an anatomical as well as a physiological subdivision of it into segments, each of which is a centre of nervous action independent of the rest, yet so connected with them that the functions of all are made to harmonize in the most perfect manner.

The subdivision which the external anatomy indicates, although not perfectly coincident with that which the differences of function would suggest, has been so long sanctioned by usage and is so convenient for description, that no advantage would be gained by adopting any other. Our description of the cerebro-spinal centre, or axis as it has also been called, will be given under the following heads: 1. the spinal cord; 2. the encephalon, including *a*, the medulla oblongata; *b*, the mesocephale; *c*, the cerebellum; *d*, the cerebrum.

1. OF THE SPINAL CORD.—Syn. *Spinal marrow, Medulla spinalis;* Fr. *La moëlle epinière;* Germ. *Das Rückenmark.* The following are the anatomical limits which may be assigned to the spinal cord. It occupies a large portion of the spinal canal, terminating inferiorly at a point which, in different subjects, ranges between the last dorsal and the second lumbar vertebra. Below this point the sheath formed by the dura mater contains that leash of nerves which is called the *cauda equina*, in

the centre of which lies the filiform prolongation or process of the pia mater. The superior limit of the spinal cord is marked by the plane which lies between the occipital foramen and the first vertebra of the neck. A section made in the direction of this plane separates the spinal cord from the medulla oblongata. Immediately above this plane the decussation of fibres of the anterior pyramids takes place, and may be regarded as the natural inferior limit to the medulla oblongata.

Such is the position of the spinal cord in the adult. In the fœtus at the third month of intra-uterine life, it occupies the whole spinal canal, and extends quite to the point of the sacrum. At this early period the os coccygis consists of seven vertebræ. Coincident with its reduction to its normal number of segments, is the retraction of the spinal cord within the spinal canal. If the ascent of the cord be arrested, the fœtus is born with a tail, for the changes of the coccyx become arrested also. It is remarkable that among the inferior animals there is a direct proportion between the length of the spinal cord and that of the tail. The shorter the former, or the higher in the spinal canal it may be, the less will be the latter. In animals with long tails there is no *cauda equina*, as is the case in the ox, the horse, the squirrel, &c. and the opposite is likewise true, namely, that in animals with a short tail the spinal cord is much shorter and is placed higher up in the spinal canal. In the embryo of the bat, which has a tail, the spinal cord extends downwards, but when it loses its tail the cord appears to occupy a much smaller portion of the spinal canal. In the tadpole of the frog, likewise, the spinal cord extends into the tail, but when the tail has disappeared the cord occupies only a portion of the spinal canal.*

In point of shape, the spinal cord is cylindroid, slightly flattened on its anterior and posterior surfaces, more so on the former than on the latter. At its inferior extremity it gradually tapers to a point. Sometimes, however, we observe a small tubercle immediately above this pointed extremity, situated on the posterior surface. The perfect cylindrical form of the cord is destroyed, not only by this pointed termination and the flattening before and behind, but likewise by a marked change of dimensions in certain regions. In the cervical region we observe a distinct swelling or enlargement, which begins a short distance beneath the medulla oblongata, and gradually passes into the dorsal portion, which is the smallest, as well as the most cylindrical part of the cord. This cervical enlargement (*intumescentia cervicalis*) begins opposite the third cervical vertebra, and ends about the third dorsal. The cord continues of a cylindrical form as low as about the ninth or tenth dorsal vertebra, and then passes into the lumbar swelling (*intumescentia lumbalis vel cruralis*), which occupies a space corresponding to about two vertebræ. This swelling is both shorter and of less diameter than that in the region of the neck. The inferior extremity of the spinal cord tapers rather suddenly, and at its point is enclosed in the commencement of the filiform prolongation of the pia mater.

The bulk of the spinal cord is in the direct ratio to that of the body throughout the vertebrate series. And not only is this true with regard to the whole cord, but with respect to its segments. For when any segment supplies nerves to a greater sentient surface, or to more numerous or more powerful muscles than another, it exhibits a proportionally greater size. It is thus that we may satisfactorily explain the occurrence of the cervical and lumbar enlargements. Both supply nerves to the extremities, whilst the dorsal portion furnishes them only to the trunk. The upper extremities enjoy, in part, a high degree of tactile sensibility, and they possess great power and extent of muscular movement. That portion of the cord therefore from which the nerves to the upper extremities proceed is larger in every way than that which supplies the lower extremities, which, although provided with large and powerful muscles, do not enjoy such a range or variety of motion as the upper extremities, nor are they endowed with so exquisite a sensibility.

There are many interesting facts among the lower animals which illustrate and confirm this law. Thus, in animals which have no limbs, as serpents, the cord is of equal size throughout, excepting at its pointed extremity. It is said that in the fœtus, before the developement of the limbs, no distinction of size can be discovered in the cord, and in persons in whom an arrest in the developement of the upper extremities has taken place, there is no cervical enlargement. Cruveilhier refers to the case of the tortoise as strongly confirmatory of this law. That portion of the spinal cord which corresponds to the carapace, which is equally devoid of sensation and motion, is reduced to a mere thread, whilst those segments between which it lies, and from which the nerves of the extremities emanate, are of size duly proportionate to their muscular activity and their sensibility. In Fishes, the enlargements correspond to the fins which are possessed of greatest muscular power. In the gurnard there exist certain very remarkable ganglionic swellings, situate on the posterior part of the cervical segment of the cord. With these swellings nerves are connected, which are distributed to organs placed immediately behind the head on the lower part of the body. These organs are endowed with much tactile sensibility, and seem to serve the office of feelers, as the animal gropes along the bottom of the sea.

The length of the spinal cord in the adult is from sixteen to eighteen inches, according to the statement of Cruveilhier. Its circumference measures twelve lines at the smallest and eighteen lines at the most voluminous part. Chaussier states that its weight is from the nineteenth to the twenty-fifth part of that of the brain in the adult, and about the fortieth

* Cuvier's Report upon Serres' work, Sur l'Anat. Comp. du Cerveau. Par. 1824.

part in the new-born infant. The actual weight of the spinal cord in an adult male may be stated to be a little more than one ounce.

We may here again notice the interesting fact that there is a great disproportion between the size of the spinal cord and that of the vertebral canal, and that consequently a considerable space is found between the cord and its membranes which is occupied by the cerebro-spinal fluid.

The consistence of the medullary substance of the spinal cord, in the fresh state, is of much greater firmness than that of the brain. This lasts, however, but for a very short time, for decomposition sets in quickly, and then the cord acquires a pultaceous consistence, and the nervous matter may be easily squeezed out of the sheath of pia mater in which it is enclosed.

The pia mater adheres very closely to the surface of the cord, as intimately as the neurilemma to a nerve. In order to examine the surface of the cord, the best mode of proceeding is to dissect off the pia mater carefully, the cord having been fixed under water. The dissector will then perceive that numerous minute vessels, accompanied by delicate processes of the membrane, penetrate the cord at all points from the deep surface of the pia mater, and to this is due the adhesion of this membrane above-mentioned. This arrangement may also be shewn by dissolving out the nervous matter through the action of liquor potassæ. The prolongations from the deep surface of the sheath may be shewn by floating the preparation in water.

The spinal cord is penetrated both on its anterior and posterior aspect by fissures, each of which corresponds to the median plane. They are separated from each other by a transverse bilaminate partition of white and grey matter, of which the grey layer is posterior. This serves to connect the equal and symmetrical portions into which the cord is divided by these fissures.

The *anterior* fissure is very distinct and easily demonstrated. A folded portion of the pia mater may be traced into it down to the commissure. The edges of this fold, as it enters the fissure, are connected by a band of white fibrous tissue, which may be traced through the whole length of the cord on the exterior of the pia mater, and indicates precisely the position of the anterior fissure, and which covers the anterior spinal artery. When this fold is carefully removed, the floor of the fissure becomes apparent, formed of a lamina of white nervous matter. This layer is perforated by a great number of minute orifices, which give to it quite the cribriform character, and are for the reception and transmission of bloodvessels. In many parts the layer appears to be composed of oblique and decussating fibres, as if the same kind of decussation which occurs at the lower part of the medulla oblongata extended through the whole length of the cord. There is not, however, any real decussation: the appearance of it results from the foramina not being always on the same level. For, in those places where they lie quite on a level with each other, no one could suppose that such an arrangement of fibres existed. Here, as elsewhere, the fibres assume the transverse direction. The depth of the anterior fissure is not the same all down the cord; it gradually diminishes towards its lowest point; its deepest part, however, corresponds to the cervical enlargement, and here it is about one-third of the thickness of the cord measured from before backwards.

The whole cribriform layer which forms the floor of the anterior fissure constitutes a commissure between the lateral halves of the cord in their whole length. It is called the *anterior* or *white commissure* of the cord.

The *posterior* fissure is very much finer and more difficult to demonstrate than the anterior. It is not penetrated by a *fold* of the pia mater: a single and very delicate layer of that membrane is continued from its deep surface down to the floor of the fissure. It is at this situation that the spinal pia mater assumes the appearance and character of that of the brain. Here and there, within the fissure, the pia mater appears interrupted and the vessels extremely few, and in such situations the fissure becomes very indistinct and difficult to recognise. The process of pia mater becomes extremely delicate towards the lowest extremity of the cord. The posterior fissure is deeper than the anterior. Through a great part of its course it is equal to fully one-half of the thickness of the cord; in the lumbar region, however, its depth is very much less. Its floor is formed by a layer of grey matter, which connects the cineritious matter of each lateral half of the cord, and which is called *the grey commissure*. In the lumbar region, however, it does not appear to reach the grey commissure.

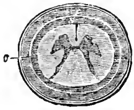
Arnold denies the continuity of the posterior fissure through the greater part of the cervical and dorsal regions. According to his figures it ceases on a level with the second cervical nerve and reappears about the second dorsal vertebra. This does not at all accord with my observation, nor is it confirmed by any anatomist that I know of. It appears to me that the continuity of the fissure might be more properly questioned at the lowest third of the cord, where it is often so feebly developed as to elude detection. In three out of four specimens now before me, the fissure is sufficiently distinctly marked down to quite the lowest extremity of the cord, and the posterior columns separate readily from each other along it. In the fourth, which is quite recent, the fissure at the lowest part of the cord is only to be distinguished here and there by a solitary red vessel passing to the grey commissure, and is most distinct in the cervical region. Those specimens which shew it well have been hardened in a preserving liquid, which, by constringing the substance of the posterior columns, renders the fissure much more distinct. There seems little doubt that the posterior columns have no connexion with each other as far down as the lumbar region. Below that, however, it is not improbable that they may be united across the middle line, and that to this cause the indistinctness of the posterior fissure may be due. And this anatomical fact may be quoted as, in some degree, adverse to the theory which regards these columns as sensitive: for were they columns of sensation, it is probable that the preservation of their distinctness would have been more fully provided for.

The anterior and posterior fissures, as Cruveilhier remarks, leaving on each side a perfectly symmetrical organ, serve to demonstrate the existence of two spinal cords, one for each side of the body, and both presenting a perfect resemblance of form and structure.

There are no other fissures in the cord besides those just described. Several anatomists regard the lines of origin of the anterior and posterior roots of the nerves as constituting distinct fissures. But a little careful examination will readily convince any one that there is no real separation of the nervous substance of the cord corresponding to these lines, and that there is no anatomical indication of a subdivision into columns or segments in connexion with them. When the roots of the nerves have been removed on each side, nothing is seen but a series of foramina or depressions corresponding to the points of emergence of the nerve-fibres, of which the roots are composed.

The most natural subdivision of the spinal cord is that which is obviously indicated by its internal structure. In examining a transverse section (*fig.* 376), we observe that the interior

Fig. 376.



of each lateral portion is occupied by grey matter, disposed somewhat in a crescentic form. The concavity of the crescent is directed outwards: its anterior extremity is thick, and is separated from the surface of the cord by a considerable layer of white nervous substance. The grey matter is prolonged backwards and outwards in the form of a narrow horn, which reaches quite to the surface of the cord, and near the surface experiences a slight enlargement. This posterior horn constitutes, on each side, a natural boundary between the two columns of which each lateral half of the cord consists. All that is situate in front of the posterior horns is called the *antero-lateral* column, and this comprehends the white matter forming the sides and front of the semi-cord, limited anteriorly by the anterior fissure and posteriorly by the posterior roots of the nerves. The posterior column is situate behind the posterior horn of grey matter, and is separated from its fellow of the opposite side by the posterior fissure.

According to this view, then, the spinal cord will be found to consist of four columns, between which an obvious line of demarcation exists throughout the whole length of the organ. These are two *antero-lateral* columns and two *posterior* columns. The former constitute by far the largest proportion of the white substance of the cord, and they envelope the anterior obtuse portion or horn of the grey matter. The white commissure at the bottom of the anterior fissure unites them. The anterior roots of the nerves are connected with them, and the posterior roots adhere to them when the cord is split up along the plane of the posterior horn. The posterior columns are small, in section triangular, placed in apposition with each other by their inner surfaces. Their apices are directed forwards, and their bases, which are slightly curvilinear, backwards. No distinct commissure of white fibres can be detected uniting these columns, save, perhaps, in the lumbar region. The connexion of the posterior roots of the nerves with them must necessarily be very slight, as they invariably separate from them in the longitudinal splitting of the cord.

The arrangement of the grey matter in the cord, as already partly explained, is as follows: In each lateral half there is a portion of grey matter, which is crescentic in form, having its concavity directed outwards and its convexity inwards towards its fellow of the opposite side. The anterior extremity or horn of the crescent is thick and roundish, and its margin has a jagged or serrated appearance, which is more conspicuous in some situations than in others. The posterior horn is directed backwards and a little outwards: it reaches the surface of the cord, and near its posterior extremity it presents a swollen or enlarged portion, which differs in colour and consistence from the rest of the crescent, being somewhat paler and softer. This portion of grey matter has been called by Rolando *substantia cinerea gelatinosa.* It is that part of the grey matter which appears to be more immediately connected with the posterior roots of the nerves.

There is an exact symmetry between the grey crescents of opposite sides, and they are united by means of the grey commissure, a layer which extends between the two crescentic portions, being attached very nearly to the central point of each. This commissure, then, when examined in its length, forms a vertical plane of grey matter, extending throughout the whole of the cord. The lateral portions are solid masses of grey matter, with which the nerve-tubes of the white substance freely intermingle, and in which, as in the grey matter elsewhere, very numerous bloodvessels ramify. There seem to be no good grounds for the opinion advanced by Mayo that these crescentic portions are hollow capsules. It was supposed by this anatomist that each crescent resembled the dentated body in the cerebellum or that in the corpus olivare; but careful examination must convince any one who takes the trouble of it that such is not the fact. It is true that the grey matter contains white fibres, but they mingle with its elements and are not enclosed within a layer of it, as described and delineated by Mayo.

When sections of the spinal cord in different regions are examined, they are found to exhibit differences of dimensions affecting both the white and the grey matter, and remarkable varieties as regards the shape of the lateral portions of the latter. The relative proportion of the grey matter to the white appears to be much greater in the lumbar than in the cervical or dorsal regions. In the upper part of the cord the crescentic portions are narrow, and the white matter is abundant. The posterior horn appears as a thin lamella extending back to the surface, while the anterior is a small, roundish, slightly stellate mass, remote from the surface of the anterior columns. In the dorsal region the grey matter is at its minimum of developement: here it appears much contracted and diminished in size, although presenting the same general form as that in the region of the neck. In the lumbar region both horns acquire a manifest increase of thickness, the posterior still extending back quite to the surface, and the anterior, more stellate than in the higher parts of the cord, separated from the corresponding surface of the cord by a much smaller quantity of white substance. At a still lower part of the cord, where the lumbar swelling begins to diminish in size, the posterior horn is short and thick, and sometimes seems not to reach quite back to the surface of the cord,—an appearance, however, which might be produced by some accidental obliquity of the section; and its posterior extremity has somewhat of the form of a hook, its hindermost portion being directed a little forwards and inwards, forming a very sharp angle with the rest of the grey substance which constitutes the horn. At the lowest part of the cord the crescentic form of the lateral portions of grey matter ceases, and the transverse section of it presents the form of a solid cylinder slightly notched on each side, and surrounded completely by the white substance. (*Fig.* 377.)

There are also differences deserving of notice as regards the white substance in the different regions of the cord. The largest quantity of white substance is found in the cervical enlargement, as may be shown on a transverse section. Both the antero-lateral and the posterior columns are large, but by far the greatest proportion of the mass of white substance must be assigned to the antero-lateral columns. It is also important to remark that the quantity of white substance which is placed between the posterior horns in a great part of the cervical region is augmented by the existence of two small columns of white matter, which will be more particularly described when we come to speak of the medulla oblongata. These columns extend from the inferior extremity of the fourth ventricle, very nearly as far down as the termination of the cervical enlargement, where they gradually taper to a fine point and disappear, allowing the posterior columns of the cord to come into apposition along the posterior fissure. These small columns, *the posterior pyramids* of some authors, do not appear to be completely isolated from the proper posterior columns of the cord. There is generally a very clear line of demarcation between them, visible on the posterior surface, by a distinct depression or fissure which passes in the length of the cord; but this fissure does not extend much deeper than the surface, nor does any distinct process of pia mater sink into it. Nevertheless, in the spinal cord, which has been hardened in alcohol or by any other chemical reagent, these columns will readily separate by tearing in the longitudinal direction, both from each other and from the posterior columns between which they are placed. They occupy rather less than one-half of the interval between the posterior roots of the nerves, excepting at their lowest part, where, from their tapering form, they obviously take up much less space.

Fig. 377.

A, anterior surface.
P, posterior surface.

In the dorsal region both white and grey matter are small in quantity; the posterior columns, however, do not appear to experience a diminution in size at all commensurate with the general shrinking of the organ in this region, nor with the reduced size of the antero-lateral columns.

In the lumbar region the antero-lateral columns are small; the grey matter is large in quantity, and the posterior columns appear to retain their size: they are, indeed, proportionally to the other parts of the cord, larger in this than in the cervical region, and the lumbar swelling appears to depend much more upon the large size of the grey matter and of the posterior columns than upon the bulk of the antero-lateral ones. At the lowest point of the cord the white matter has gradually disappeared, and in the commencement of the terminal filiform process grey matter only is present, according to Remak and Valentin.

These facts lead to some interesting physiological conclusions bearing upon the function of the cord as well as of its columns. It is in the upper extremities that voluntary power and sensibility are in their most highly developed state, and accordingly the size of that portion of the cord from which the nerves of these parts emanate is greater than any other portion of the cord. Were the sensibility dependent on the grey matter or upon the posterior columns, as has been conjectured, it might most legitimately be expected that a proportionate developement of these parts would exist in the cervical region. Yet a comparison of the cervical with the lumbar swelling demonstrates that the developement of both the grey matter and the posterior columns, (if not absolutely, certainly relatively to the bulk of the segment,) is inferior in the former to that in the latter, whence nerves are supplied to the inferior extremities in which sensibility is much less acute, and in which there is a much less perfect adjustment of the voluntary power to the muscular movements.

The difference of the respective sizes of the antero-lateral columns in those parts of the cord which supply the upper and lower extremities is perfectly consistent with the difference in the sensibility and voluntary power of those parts.* And as in the trunk these endowments are at their lowest point of developement, so the dorsal region of the cord is that which exhibits the antero-lateral columns of the smallest bulk.

In the lower parts of the body, which receive their supply of nerves from the lumbar swelling of the cord, there are certain peculiarities worthy of the attention of the physiologist. Thus the sphincter muscles of both the bladder and rectum are to a great degree independent of voluntary influence, and act independently of consciousness. The principal function of the lower extremities is that of locomotion; they are the pillars of support to the trunk, and the chief agents in the maintenance of its attitudes. And, although in these actions the will exercises a not inconsiderable control, still the principle of purely physical nervous action renders them in a great degree independent of the mind.† The reflex or excito-motory actions are much more evident in the lower than in the upper extremities; the former are much more independent of cerebral lesion than the latter. And let it be remarked that these phenomena are associated with high developement of grey matter, and with posterior columns of large size, while the antero-lateral columns are comparatively small. May not the high developement of the grey matter have reference to the exalted state of the physical nervous actions of the lower part of the body, and that of the posterior columns to the locomotive actions? To these points we shall have again to refer when we discuss the functions of the spinal cord.

Is there a central canal in the spinal cord? Many anatomists have affirmed that the spinal cord was traversed in its entire length by a canal, which was continuous with the fourth ventricle. If such a canal exist, it must be extremely difficult to demonstrate, as I have never, after numberless examinations, been able to see it. In transverse sections of the spinal cord, which have been dried upon glass, there is sometimes an appearance which may be attributed to the presence of a minute canal; but I should be more disposed to ascribe it to the patulous mouth of a bloodvessel which had been divided in making the section, for it is by no means constant even in different regions of the same spinal cord. The situation which some have assigned to this supposed canal is between the grey and white commissures; but Stilling and Wallack* place it in the grey matter. It is obvious that an artificial separation of these layers, which is easily effected, and more especially while the preparation is being dried, would give rise to the appearance of a canal upon a transverse section. It may be stated, further, that the deepest part of the longitudinal fissure is wider than any other portion of it, and, if cut across, might appear like a canal.

The observations of Tiedemann appear to me to put this question in its true light. I shall, therefore, make the following quotation from his learned work on the anatomy of the fœtal brain, without, however, subscribing to the accuracy of all the statements it contains.

"The spinal marrow," says Tiedemann, "represents a hollow cylinder, the thin walls of which are bent backwards, the posterior part representing a longitudinal opening; for it is hollowed by a groove, termed *the canal of the spinal marrow*. This canal exists through the whole cylinder, and communicates with the calamus scriptorius, with the fourth ventricle, which, strictly speaking, is but a dilatation of it. During the first periods we can, without difficulty, separate the thin and flexed walls of the spinal marrow, and thus expose the canal which they contain. This canal is somewhat broader in those points where the spinal marrow sensibly enlarges exteriorly, as at the origin of the nerves for the pectoral and abdominal extremities. The mechanism of its formation is very simple: the pia mater, acquiring more extent, is folded longitudinally backwards and dips into the substance of the spinal marrow, which, as we have seen, had been previously in a fluid state. It is very evident that, in the commencement of the second, third, and even fourth months, this canal has, in proportion to the thickness of the walls of the spinal marrow, a much greater capacity than it subsequently acquires. The contraction which it undergoes in the progress of the developement of the embryo, arises from the pia mater depositing a new substance, the materials of which it derives from the blood sent by the heart, and which, augmenting the volume of the walls of the cylinder, ought necessarily to diminish the calibre of the central canal. This substance is soft, reddish, and traversed by numerous small vessels during the period of the last two months. We cannot doubt, then, that the grey substance of the spinal marrow has an origin subsequent to that of the medullary

* Weber's experiments sufficiently indicate that the general as well as the tactile sensibility of the lower extremities is considerably inferior to those of the upper extremities.

† See the observations at the commencement of the article, p. 589.

* Untersuchungen über die Textur des Rückenmarks. Leipz. 1842.

fibrous substance, and that it is applied from within outwards on the surface of this latter. Consequently, the opinion of M. Gall, that it is formed prior to the medullary, and is, as it were, the matrix, is absolutely false with regard to the spinal marrow, for we already perceive the roots of the spinal nerves, in the second and third months, although at this period there is no cortical yet deposited in its canal."

"It is very remarkable that the canal of the spinal marrow exists constantly and during the entire life of the animal, in fishes, reptiles, and birds. I have met it in a great number of fishes, both of salt and fresh water, such as the ray *(Raia)*, shark *(Squalus)*, bream *(Cyprinus brama)*, bandfish *(Cepola)*, pike *(Esox)*, salmon, carp, &c.; and I have always found its internal surface covered with a layer of grey substance. The observations of M. Arsaky agree perfectly with mine in this respect."*

"I have observed the same canal, in question, in the hawk's-bill tortoise, common tortoise, a young crocodile of the Nile, wall lizard, ringed snake, land salamander, green frog, and the common toad. In front it is continuous with the fourth ventricle, or rather it dilates to give origin to this cavity, and its interior was covered with a thin layer of cortical substance."

"Birds possess this canal both in their embryo state and in adult age. In these it forms, at its inferior part, a remarkable excavation, which Steno, Perault, Jacobœus, and some other authors have described under the name of the rhomboidal sinus. In birds, also, the grey substance occupies the interior, and is no where in greater abundance than on the walls of this sinus."

"The canal equally exists in the spinal marrow of the fœtus of mammiferous animals, as also in the young animals of this class (?) F. Meckel has found it in the embryo of the rabbit;† and G. Sewell in young animals of the genus dog, sheep, ox, and horse.‡ This latter writer observes that it was filled with a colourless fluid, nearly opaque, and of the same nature as that which existed in the ventricles. F. Meckel has even met a small canal full of fluid in the spinal marrow of some of the adult mammiferous class, such as the dog, cat, rabbit, sheep, and ox. Blaes has met it also in many adult mammiferous animals.

"Although we cannot find this canal in the spinal marrow of the human adult in its normal state of developement, still it has undoubtedly been met with; we should, then, consider it as the result of a retardation in its developement. Charles Stephen§ was the first who gave a description of it; and Columbo,|| Piccolhomini,* Bauhin,† Malpighi,‡ Lyser,§ Golles,|| Morgagni,¶ Haller,** and M. Portal,†† have since observed it. Many of these writers have even considered it as a constant and normal disposition; an hypothesis which Varoli, Monro, Sabatier, and some other anatomists have justly opposed. Nymman proceeded even still further, for he spoke of two canals prolonged into the spinal marrow. Gall pretends to have found in the spinal marrow of new-born infants, in infants of a certain age, and even in certain adults, two canals free from all communication with the fourth ventricle, but which extended through the pons Varolii, the tubercula quadrigemina and the medulla oblongata into the interior of the optic thalami, where they formed a cavity sufficient to lodge an almond! These two supposed canals, with their termination in the optic thalami, do not exist; we must suppose that they are produced by a forced insufflation: I have never met them either in the adult or in the fœtus; nor do we find them in animals in which the canal of the spinal marrow always communicates with the fourth ventricle, by means of the calamus scriptorius."‡‡

We shall notice further on the recent statement of Stilling and Wallack on this subject.

Bloodvessels of the spinal cord.—The arteries of the spinal cord are derived from the vertebral arteries as well as from the small vessels which ramify upon the spinal column in the cervical, dorsal, and lumbar regions.

Of these the largest and most important are the two spinal arteries which spring from the vertebral on each side, distinguished as the *anterior* and *posterior* spinal arteries.

The *anterior* spinal artery is the larger of the two. It arises from the vertebral artery near to the basilar: sometimes it comes from the basilar itself, or from the inferior cerebellar; and sometimes the arteries of opposite sides have different origins, one arising from the vertebral and the other from the basilar. It passes nearly vertically downwards, inclining inwards, in front of the medulla oblongata, and having passed for a short distance in front of the cord, it unites at an acute angle with its fellow of the opposite side, forming a single vessel, which passes down in front of the anterior median fissure, under cover of the band of white fibrous tissue which is found along the middle of the anterior surface of the cord. The artery thus formed is called the *anterior median artery* of the spinal cord.

"The anterior or median spinal artery," says Cruveilhier, "therefore, results from the anas-

tomoses of the two anterior spinal branches of the vertebral. In one case there was no artery on the left side, but the right was twice as large as usual. The vessel is of considerable size until it has passed below the cervical enlargement of the cord, from which point down nearly to the lumbar enlargement it becomes exceedingly delicate; a little above the last-named enlargement it suddenly increases in size, again gradually diminishes as it approaches the lower end of the spinal cord, and becoming capillary is prolonged down to the sacrum, together with the fibrous string in which the spinal cord terminates."

"During its course this artery receives lateral branches from the ascending cervical and the vertebral in the neck, and from the spinal branches of the intercostal and lumbar arteries in the back and loins. Those branches penetrate the fibrous canal formed by the dura mater around each of the spinal nerves; become applied to the nervous ganglia to which they supply branches, yet intermixed with and follow the course of the corresponding nerves; send small twigs backwards to the posterior spinal arteries, and terminate in the anterior spinal trunk at variable angles, similar to those at which the nerves are attached to the cord."*

The posterior spinal arteries arise from the vertebral or from the inferior cerebellar artery: they incline backwards to the posterior surface of the spinal marrow, along which they descend in a tortuous manner, anatomosing freely with each other and with the small arteries which accompany the nerves in the intercostal foramina. A network of vessels surrounds each posterior root of a spinal nerve, derived from ramifications of those arteries. We can trace the posterior spinal arteries as low down as the lumbar region, distinct throughout their entire course.

Veins.—The blood is returned from the spinal cord by a venous plexus which emerges from the pia mater and is spread over its whole surface: opposite the roots of each nerve a small vein is formed, which passes outwards with the nerve in the same sheath, and empties itself into the large vein which is situate in the intervertebral foramen. Veins accompany the anterior and posterior spinal arteries in the upper part of their course. Branches from this plexus frequently pass to the dura mater involved in a fold of arachnoid, and thus communicate with the general plexus which surrounds the sheath.

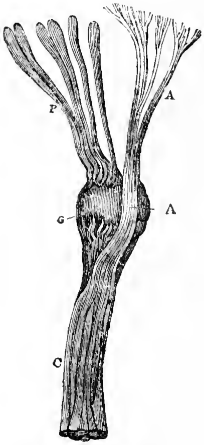
We observe that the arteries of the spinal cord are reduced to a very minute size before they penetrate the substance of that organ. The largest vessels are therefore found on its surface or in its fissures. And it may be further remarked that when vessels of a size to be readily detected by the naked eye penetrate the substance, numerous foramina, produced by the separation of the nervous fibres, become distinctly visible. This is very obvious in the white commissure.

The purpose of such a minute subdivision of bloodvessels, prior to their entrance into the substance of the cord, must evidently be to guard the nervous substance against the impulse of several columns of blood of large size. A similar provision, made in a more conspicuous manner, is manifest in the brain, and will be noticed by-and-bye.

Of the spinal nerves.—There is a pair of spinal nerves for each intercostal foramen, and for that between the atlas and occiput. We can thus enumerate in all thirty-one pair of nerves having their origin from the spinal cord, and this number is exclusive of the spinal accessory nerve which is connected with the upper part of the cervical region.

The spinal nerves have the following very constant characters. Each has its origin by two roots, of which the anterior is distinctly inferior in size to the posterior. The ligamentum denticulatum is placed between these roots. Each root passes out through a distinct opening in the dura mater. Immediately after its emergence a ganglion is formed on each posterior root, and the anterior root lies embedded in the anterior surface of the ganglion and involved in the same sheath (*fig* 378), but without mingling its fibres with those of the ganglion. Beyond it,

Fig. 378.



Origin of a spinal nerve.

C, compound nerve resulting from the commingling of the fibres of both roots.

the nervous fibres of both roots intermingle, and a compound spinal nerve results. The trunk thus formed passes immediately through the intervertebral tube and divides into an anterior and posterior branch, which are distributed to the muscles and integument of the

* Cruveilhier, Anat. Descr.

trunk and the extremities. Of these branches the anterior one is generally much the larger.

An exception, however, to this arrangement occurs in the case of the first spinal nerve (the tenth pair of Willis), to which Winslow gave the appropriate name *sub-occipital nerve*, to indicate its peculiarity of character. This nerve sometimes has only one root, and that corresponds to the anterior. More generally it has two roots, of which, unlike the other spinal nerves, the anterior is the larger, containing, according to Asch, from three to five or seven bundles of filaments, whilst the posterior contains two or three, or at most four much smaller bundles. Very frequently the posterior filaments of either the right or left side unite with the spinal accessory, a slight enlargement or knot being formed at the point of junction; from this place a bundle of filaments emerges equal in size to the posterior root, and takes the ordinary course of that root, a small ganglion being formed upon it at the usual situation. Frequently, however, this ganglion is wanting. The compound nerve formed from the junction of these two roots, besides giving off communicating filaments to the sympathetic, divides as the other spinal nerves do into an anterior and posterior root, of which, however, contrary to the usual arrangement, the posterior is the larger.

The spinal nerves are arranged naturally into classes according to the regions of the spine in which they take their rise. We number eight in the cervical region, the sub-occipital included; twelve in the dorsal region; five in the lumbar, and six in the sacral regions. All the nerves, after the second, pass obliquely outwards and downwards from their emergence from the spinal cord to their exit from the vertebral canal, and this obliquity gradually increases from the higher to the lowest nerves. The roots of the nerves possess certain characters, of which some are common to all, and others are peculiar to the nerves of particular regions.

All the spinal nerves arise from the cord by separate fasciculi of filaments, which, as they approach the dura mater, converge to each other and are united together to constitute the anterior or the posterior roots. The posterior roots of opposite sides lie at a pretty uniform interval, from the upper to the lower part of the cord, indicating but a very trifling change in the thickness of the posterior columns throughout their entire course. The ganglia on the posterior roots are all proportionate to the size of their respective roots.

The characters proper to the nerves of particular regions may be stated as follows:*—

The cervical nerves exhibit much less obliquity of their roots than the other vertebral nerves. The second cervical nerve is transverse (the first passing a little upwards as well as outwards); the succeeding nerves slope downwards and outwards, the lowest being the most oblique; the obliquity, however, never exceeds the depth of a single vertebra.

The roots of the nerves in the cervical region are of considerable size. The posterior roots bear a larger proportion to the anterior than in any other part of the spine. According to Cruveilhier, the ratio is as 3 to 1, and this estimate is probably correct. It applies not only to the entire root, but to the fasciculi of filaments which enter into their formation.

The nerves in this region increase rapidly from the first to the fifth, and then maintain nearly the same size to the eighth.

The dorsal nerves, with the exception of the first, which closely resembles a cervical nerve, have very peculiar characters.

There is a manifest increase in the obliquity of the roots, so that the length of each root within the spinal canal equals the height of at least two vertebræ. And it may be remarked that the apparent obliquity is less than the real, for each root remains in contact with the cord for a short distance after its actual emergence from the substance of it, so that the point of separation is some way below the point of emergence.

The interval between the roots is greater in the dorsal region than any other segment of the cord. The bundles, which compose the roots, are smaller than elsewhere.

We observe a very slight disproportion between the anterior and posterior roots in the dorsal region. The latter, however, still maintain predominance of size.

Lumbar region.—From the dorsal region to its terminal extremity the surface of the spinal cord is covered both on its anterior and posterior aspects by the fasciculi of origin of the lumbar and sacral nerves. They emerge very close to each other upon those surfaces, and the intervals between the sets of fascicles proper to each root are extremely short, so that they form an uninterrupted series of bundles on each surface.

The proportion of the posterior to the anterior roots in the lumbar region is as 2 to 1 according to Cruveilhier, or as 1½ to 1, which seems to me to be nearer the truth. And there does not appear to be any material difference in point of size between the posterior and anterior fascicles.*

A very interesting feature in the origin of the lumbar and sacral nerves may be seen by observing the relation to each other of the anterior and posterior roots of opposite sides on the respective surfaces of the cord. The anterior roots of opposite sides may be seen to approximate the median line gradually as they descend, until at the lowest points they almost touch. On the contrary, the posterior roots continue nearly in the same sequence all the way down. It may, therefore, be supposed that in the tapering of the cord the anterior

* In the succeeding statements I have followed Cruveilhier's description, which I have verified, excepting in a few points which are specified.

* M. Blandin assigns the following proportions of the posterior to the anterior roots in the several regions; in the cervical region as 2 : 1; in the dorsal region as 1 : 1; and in the lumbar and sacral regions as 1½ : 1.

fibres of the antero-lateral columns separate most quickly from it.

The direction of these roots is almost vertical, and their length within the canal of the dura mater is very considerable. The aggregate of them forms the *cauda equina*.

I have not observed that the situation in which the ganglia of the sacral nerves are formed is different from others. They are contained, as elsewhere, in sheaths of dura mater, and lie in the sacral foramina, surrounded by fat, and from the looseness of their connection with the walls of those foramina they may be very easily detached.

I cannot confirm Cruveilhier's statement that the anterior and posterior roots in the sacral region together form the ganglia.

The roots of the sacral nerves gradually diminish in size, so that the lowest are smaller than any others which emerge from the spinal cord.

In connecting the peculiar anatomical characters of the spinal nerves in the various regions with their physiological action, some interesting points are presented to our notice.

The great size of the cervical nerves is quite in conformity with the exalted vital actions of the upper extremities. And the predominance of the posterior over the anterior roots, both positive, and as compared with other regions, corresponds with the great developement of sensation in the upper limbs.

The posterior root of the second cervical nerve, as has been noticed by Longet, is considerably larger than the anterior, as 3 : 1; and it is from this source that the occipital and mastoid nerves, the sensitive nerves of the integument in the occipital region, derive their filaments.

In the dorsal region the almost equality of the anterior and posterior roots and the small size of both is consistent with the absence of any great degree of developement either of the sensitive or motor power. Or if, as there is some reason for believing, many of the movements in that segment of the body which is supplied from this region of the cord be of the excito-motory kind, then we might suppose that each posterior root contains an excitor filament for each motor one in the anterior root; and if the sensitive fibres are superadded to the former (allowance being made for the smaller size of sensitive fibres,) the slight predominance of the posterior root may be accounted for.

Lastly, the increased muscular activity of the lower extremities and their greater sensibility as compared with the dorsal segment, renders necessary the increase of size which the roots of the lumbar and sacral nerves experience. And it may be conjectured that the predominance of the posterior roots has reference to the exalted sensibility of some parts of the lower limbs.

One of the most important problems in the anatomy of the spinal cord is to determine the precise relation which the roots of the nerves bear to the columns of the cord and to the grey matter. As far as coarse dissection enables me to determine, I would venture to make the following statement, founded upon my own observations.

The anterior roots derive their fibres wholly from the antero-lateral columns. Of these fibres it is probable that some are continuous with the longitudinal fibres of the cord, and that others pass into the grey matter. This, however, is very difficult, if it be possible, of demonstration by the ordinary modes of dissection. The posterior roots adhere to the posterior part of the antero-lateral columns, and derive their fibres chiefly from that source. I have never, in numerous dissections, seen any thing to induce me to believe that the posterior columns contribute to the formation of the posterior roots. If they do, it must be by few and extremely delicate fibres. It seems highly probable (although the demonstration of the fact is attended with great difficulty) that the fibres of the posterior roots have a similar disposition to that described for the anterior, and that some pass into the posterior horn of the grey matter, and others are continuous with the longitudinal fibres.

Various conflicting statements have been made by the anatomists who have written upon the spinal cord, with regard to the actual connection of the roots of the nerves with the proper substance of the organ. Nor is this to be wondered at, when we consider the great delicacy of the investigation. It is very easy to trace any set of filaments to the pia mater; but after they have passed beyond that covering, the nervous fibres lose their main support and their bond of union, and they separate from each other. Their exquisite delicacy and microscopic size render any further dissection of them extremely difficult. Mr. Grainger, in his excellent treatise on the spinal cord,* recommends certain precautions which I have adopted with advantage. The cord should be examined *immediately after death*, as the delay even of a few hours increases the softness of the medullary substance. Great advantage is derived from placing the cord, immediately after its removal, in a very weak mixture of alcohol and water, as by these means firmness is given to the parts without rendering them crisp and brittle, as happens if strong alcohol be used. The parts should be dissected with very fine instruments under water. "I have met with most success," says Mr. Grainger, "by dividing the pia mater at the median fissure, and very cautiously raising it as far as the lateral furrow, leaving its connection with the fibres of the nerves intact; it is then necessary to open either the anterior or posterior lateral fissure according to the root examined, at a little distance above the exact place where the nerve which is to be dissected is attached to the cord, when by cautiously proceeding to open the fissure, the threads which dip into the grey matter are perceived." Mr. Grainger recommends the adoption of a similar mode of dissection for the cranial nerves, care being taken in every case not to disturb the connec-

* Observations on the Structure and Functions of the Spinal Cord, p. 37. Lond. 1837.

tion of the pia mater with the nervous fibres themselves. He also very properly cautions the dissector against a deceptive appearance connected with the passage of those blood-vessels which enter the lateral fissure, in order to reach the internal grey substance. "Without due precaution," he adds, "these vascular branches may themselves be readily mistaken for nervous fibrils; but they are especially liable to be productive of error, because, when they are made tense, they cause those portions of the longitudinal fibres of the cord, which are left between them to assume exactly the appearance of flat transverse fibres; this circumstance probably misled Gall, and induced him to suppose that all the fibres of the spinal nerves were connected with the grey substance."

The following is Mr. Grainger's account of the result of his examinations conducted with the precautions above specified.

"After repeated examinations, I satisfied myself that each root was connected both with the external fibrous part of the cord and the internal grey substance. The following is what appears to be the structure: after the two roots have perforated the theca vertebralis, and so reached the surface of the cord, it is well known that their fibres begin to separate from each other; of these fibres, some are lost in the white substance, whilst others, entering more deeply into the lateral furrows, are found to continue their course, nearly at a right angle with the spinal cord itself, as far as the grey substance in which they are lost. But this arrangement has no resemblance to the distinct division into fasciculi, depicted by Mr. Mayo; on the contrary, it is with great care only that small, delicate, individual threads or striæ, as it were, are traced, dipping into the lateral fissure, and at length joining the grey matter. This difficulty is owing to the fact that whilst the fibres on the outer surface of the pia mater adhere very intimately with that strong membrane, on its inner surface, the membrane becomes so extremely delicate, that the fibres lose much of their firmness, and break on the application of the least force; an accident which always happens if the pia mater be raised from the surface of the spinal cord, beyond the point where the nerves are attached. When the filaments have penetrated into the fissure, they lose their rounded figure and become flattened, and are then seen passing to the grey substance at a right angle to the longitudinal fibres. It is extremely difficult, owing to the delicacy of the parts, to determine the exact relations which exist between the above filaments and the grey matter; but in a few dissections I have been able to perceive these fibrils running like delicate striæ in the grey substance. In one instance the fibres, being more distinct than usual, an appearance was presented having a remarkable resemblance to that which is seen on making a section of the corpus striatum in a recent brain, after the method of Spurzheim. My friend and colleague, Mr. Cooper, in this case counted distinctly five separate fibrils passing from the anterior root of one nerve, and there were some other fibres derived from the same root, which were not so plainly seen."

"From numerous examinations," continues Mr. Grainger, "I am induced to believe that whenever the white fibres of the nervous system become connected with the grey substance, whether in the different masses of the brain, in the spinal cord, or in the ganglions, the arrangement is similar to what is seen in the section of the corpus striatum to which reference has just been made. The fibres become as it were encrusted with the grey matter, a disposition which may even be seen by a careful inspection in the convolutions of the cerebrum, in which the radiating fibres of the crus cerebri are observed like delicate striæ."

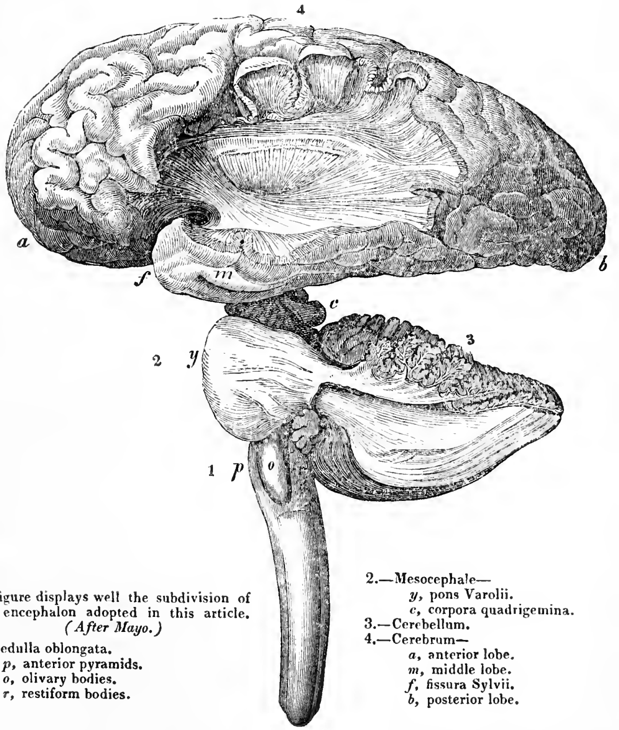
I have repeated the dissections of the roots of the nerves in the manner described by Mr. Grainger, and am enabled to confirm his general results. It appeared to me, however, that considerably the greater number of the fibres passed in at right angles, whilst those which might be supposed to take an upward course were few and indistinct, and seemed rather to pass obliquely inwards and slightly upwards than to approach the vertical direction. In short, when the fibres had penetrated the medullary substance, they seemed to diverge from one another,—those which occupied a central position preserving much more of parallelism than either the upper or the lower ones. It is extremely difficult to demonstrate the direct continuity between the fibres of the nervous roots and those of the cord. Valentin has, indeed, depicted the transition of nerve fibres into the spinal cord (see *fig.* 330, p. 592) as seen by the microscope; but these may be passing to the grey matter of the cord. The continuity of the fibres of the nerves with the longitudinal fibres of the cord would probably take place at the surface of the latter in greater numbers than at more deeply-seated planes. In the dissections above described, such fibres would be very apt to be destroyed or to be overlooked. Mr. Grainger, in the work before referred to, speaks evidently with much greater confidence of the connexion of the roots of the nerves with the grey matter than of their continuity with the longitudinal fibres. He expresses his conviction, however, that such a continuity does exist, although the exact mode of connexion and the situation at which it occurs cannot be demonstrated.

This question, respecting the precise relation of the roots of the nerves to the cord, is one of those in which physiology in a certain sense takes the lead of anatomy. Experiment has made it certain that while the spinal cord serves as a propagator of nervous power to and from the brain, as in the ordinary sensations and voluntary movements of the trunk and extremities, it is likewise capable of acting as an independent nervous centre, and that movements of a very definite character may be produced in parts connected with it, even after all communication between it and the brain has been cut off. And it has been supposed by one of the most zealous labourers in this department of physiology, that a distinct series of nervous fibres is directed to each class of actions, those, namely, of sensation and volition, and those which are independent of the brain. Mr. Grainger was the first who offered a distinct solution to the anatomical problem which arose out of this hypothesis. Probable as his explanation appears to be, a candid review of the observations which have been hitherto made obliges me to state my opinion that the question is still *sub judice*, and that further research is necessary to prove unequivocally that of the fibres composing the roots of the nerves, some pass upwards and enter the brain, and others do not pass beyond the grey matter of the spinal cord. And this inquiry demands more than ordinary care, for the mind of an observer would be easily biased by so attractive an hypothesis as that above referred to.

It is not from physiological experiment nor from coarse dissections that we can expect a solution of this difficult but most important problem. We must look to the microscopical analysis of the anatomical elements of the spinal cord, as well as of the encephalon, for the most exact results upon all questions connected with the working of these centres. In a subsequent part of the article I shall give an account of the present state of our knowledge of this most interesting subject, having first examined the coarser anatomy of the several parts of the encephalon.

2. Of the Encephalon. Gr. εγκεφαλον or εγκεφαλος (εν τη κεφαλη); Fr. *l'Encephale, le cerveau;* Germ. *das Gehirn; The Brain.*—This term is used here in its strictly etymological sense to denote that part of the cerebro-spinal centre which is contained within the cavity of the cranium. Although it forms a great mass, continuous throughout, it offers certain very obvious subdivisions, which may be more conveniently described separately (*fig.* 379). Before proceeding, however, to the description of these portions, it will be necessary to take a brief review of some general points connected with the entire encephalic mass.

Fig. 379.



This figure displays well the subdivision of the encephalon adopted in this article. (*After Mayo.*)

1.—Medulla oblongata.
p, anterior pyramids.
o, olivary bodies.
r, restiform bodies.

2.—Mesocephale—
y, pons Varolii.
c, corpora quadrigemina.
3.—Cerebellum.
4.—Cerebrum—
a, anterior lobe.
m, middle lobe.
f, fissura Sylvii.
b, posterior lobe.

The size of the encephalon by no means keeps pace with that of the body. In comparing that of the four classes of vertebrate animals, we observe a manifest increase of its size as compared with the body in the following order, fishes (minimum), reptiles, birds, mammalia.* This statement, although applicable to the encephalic mass when viewed as a whole, does not apply to certain of its parts, which are often more developed in the less perfect than in the more highly organized animals. The cerebrum and cerebellum, however, exhibit this gradual increase of developement, and their enlargement is in accordance with a gradually increasing manifestation of mental faculties. And it is upon the great size of these parts that the superiority of the human brain over that of all other animals depends.

In comparing the brains of some of the larger mammalia with that of man, we observe an evident want of correspondence between the bulk of the encephalic nerves and that of the encephalon itself. This does not accord with what we have had occasion to notice respecting the spinal cord, in which large nerves were always concomitant with high developement of the organ itself. The maximum weight, as Müller remarks, of a horse's brain is, according to Soemmering, 1 lb. 7 oz.; the minimum of an adult human brain 2 lb. 5½ oz.; and, nevertheless, the nerves at the base of the brain are ten times thicker in the horse than in the human subject.

This want of correspondence between the developement of the mass of the body and that of the brain, as well as between the size of that organ and of the encephalic nerves, must surely be admitted to indicate an incorrectness in the assertion of the distinguished physiologist who has just been quoted, namely, that "all the primitive fibres of the nerves terminate in the brain; those of the cerebral nerves immediately, those of the spinal nerves through the medium of the spinal cord."† The human brain must evidently contain numerous other fibres besides those which are continuous with the roots of the nerves, and it is likely that the horse's brain contains similar ones, although less numerous; it seems, therefore, impossible that the small brain of the horse can be the point of convergence of the large spinal and cerebral nerves of that animal; and if this be true as regards the horse, it is so likewise in man. It is much more probable that a large proportion of them do not extend beyond the spinal cord, and that the greater number of the fibres of the encephalic nerves do not go beyond the part in which they are immediately implanted.

It must be admitted, however, that although this disproportion is very manifest as regards the whole encephalon, it is not so evident when we compare the nerves with those segments of the organ from which they immediately arise. Thus, the medulla oblongata is always, as regards mere bulk, in the direct ratio of its nerves; the optic lobes are large when the optic nerves are so; the olfactory lobes bear a close relation to the number of the olfactory nerves, and it may be added, to the complication of the olfactory organ. It is to the cerebral hemispheres, to the cerebellum and the systems of fibres immediately connected with them that we must attribute the disproportion in question: those parts being small when the nerves are large, as in the horse, and large when the nerves are of small size, as in man.

The human encephalon weighs about 48 oz. for the male, and 44 oz. for the female.* This estimate, which was formed by Krause, does not differ very materially from that derived from Professor John Reid's careful observations made at the Royal Infirmary at Edinburgh. The following tables are extracted from a paper by this excellent anatomist in the London and Edinburgh Monthly Journal of Medical Science for April, 1843.†

Table I.

Average weight of the encephalon, &c. between 25 and 55 years of age, in the two sexes, and the average difference between them—Males, 53 brains weighed—Females, 34 brains weighed:—

	Male. lb.	Male. oz.	Male. dr.	Female. lb.	Female. oz.	Female. dr.	Difference in favour of Male. oz.	Difference in favour of Male. dr.
Average weight of encephalon		50	3½ or		44	8½ or	5	11
	3	2	3½	2	12	8½		
Cerebrum		43	15¾		38	12	5	3¾
Cerebellum		5	4		4	12¼	0	7¾
Cerebellum, with pons & medulla oblongata		6	3¾		5	12⅓	0	7½ nearly

Table II.

Relative weight of encephalon to cerebellum, and to cerebellum with medulla oblongata and pons Varolii, between 25 and 55 years of age, in the two sexes (53 male and 34 female brains weighed).

	Male.	Female.
Relative weight of encephalon to cerebellum	as 1 to $9\frac{4}{7}$	as 1 to $9\frac{1}{4}$
Ditto to ditto, with pons and medulla oblongata	1 „ $8\frac{8}{13}$	1 „ $7\frac{9}{10}$

From this table it would appear that, in the female, the average cerebellum is, relative to the encephalon, a little heavier than in the male.

In a third table, which has been reduced from that published by Professor Reid, the average weight of the encephalon, cerebellum, with pons Varolii and medulla oblongata, is given over a much wider range of age than that in the first table quoted. For this purpose 253 brains were weighed.

* See the table at p. 623 of this volume.

† Physiol. transl. by Baly, 2nd ed. p. 796.

* According to Mr. Hamilton's investigations, the adult male brain in the Scot's head weighs, on an average, 3 lbs. 8 oz. troy; about one brain of seven is found about 4 lbs. troy; the female brain weighs 3 lbs. 4 oz.; and one of a hundred female brains weighs 4 lbs.

† Reference may also be made to an extensive series of observations on the weight of the brain by Dr. Sims, Med. Chir. Trans. vol. xix. p. 353.

From this table we are led to conclude that the brain reaches its greatest absolute weight at an early age. The maximum is found in the table at between 16 and 20; but, as Dr. Reid states, it is plain that the apparent excess of weight at this period over that for the next forty years must have arisen from sources of fallacy incidental to insufficient data. And in the group between 40 and 50, Dr. Reid states that some brains much below the average weight were found, so as to leave no doubt that the diminution in the average weight in that group was attributable to that circumstance.

A decided diminution in the average weight of the brain was noticed in females above 60 years of age; but, among the males, this was not apparent until a later period. Upon this point Professor Reid makes the following judicious observation, which I am anxious to quote as according with the views I have expressed at page 642 respecting liquid effusions. "We certainly did expect," he says, "also to find a similar diminution in the average weight of the male brain above 60 years of age, for we are perfectly satisfied, as the tables containing the individual facts will shew, that we more frequently meet with a greater quantity of serum under the arachnoid and in the lateral ventricles in old people than in those in the prime of life. We are also satisfied from an examination of the notes we have taken at the time the brains were examined, that a certain degree of atrophy of the convolutions of the brain over the anterior lobes, marked by the greater width of the sulci, was more common in old than in young persons. We have, however, frequently remarked these appearances in the brains of people in the prime of life who had been for some time addicted to excessive indulgence in ardent spirits."

The ratio between the weight of the body and that of the brain is greater in early age than at the subsequent periods. The following proportions were obtained by Tiedemann, in infants just born. In two boys the proportion of the brain to the body was as 1 : 5.15 and 1 : 6.63, and in two girls as 1 : 6.29 and 1 : 6.83. The following table gives Professor Reid's results from the examination of 92 bodies.

TABLE IV.

Relative weight of entire body to encephalon, cerebrum, cerebellum, cerebellum with pons Varolii and medulla oblongata, in 92 bodies.

* One of these was above 70 years of age.

The general conclusions deducible from the preceding statements are, that the human brain reaches and maintains its highest degree of developement between the ages of 20 and 60; that the female brain is materially smaller than that of the male; that the proportion of the weight of the brain to that of the body decreases with age, and the most marked diminution in this respect takes place between the ages of 20 and 30 years, although it has already begun at 5 years, and occurs very decidedly at from 13 to 15 years; and lastly, that the great preponderance of the human brain over that of most of the lower animals depends upon the great developement of the cerebrum and cerebellum.

It was formerly admitted, pretty generally, that the human brain was larger, both absolutely and relatively to the size of the body, than that of any other animal. This assertion, however, must now be received with some modification. Exceptions to its superiority in absolute weight are found in the elephant and the whale. The brain of an African elephant, seventeen years old, which was dissected by Perrault, weighed 9 lbs.* The brain of an Asiatic elephant weighed, according to Allen Moulins, 10 lbs.† Sir Astley Cooper dissected an elephant's brain, which weighed 8 lbs. 1 oz. 2 grs. (avoirdupois.)‡ Rudolphi found that the brain of a whale, 75 feet long, (*Balæna mysticetus,*) weighed 5 lbs. 10¼ oz., and that that of a narwhal (*Monodon monoceros,*) 17 to 18 feet long, had a weight of 2 lbs. 3 oz. And there are likewise exceptions to the statement that the human brain is larger than that of other animals, relatively to the size of his body. Pozzi§ has shewn (as quoted by Tiedemann) that many small birds (for instance, the sparrow) have, in comparison to the size of their body, a larger brain than man; and Daubenton, Haller, Blumenbach, and Cuvier, found the brain of some of the smaller apes of the Rodentia, and singing birds, relatively to the size of the body, larger than in man.||

"We must seek for the cause of man's superiority," says Tiedemann, "not merely in the greater bulk of his brain in comparison to that of his body, but regard must also be had to the size of his brain with respect to the bulk and thickness of his cerebral nerves, and likewise to the degree of perfection in its structure. Soemmering was the first to show that the human brain, in comparison to the size and thickness of the nerves, is larger than that of any other animal, even the elephant and whale, both of which have an absolutely larger brain than man. Blumenbach's, Obels', Cuvier's, Treviranus', and my own researches have sufficiently corroborated this. It is also satisfactorily shewn that the organization of the human brain is far superior to that of any other animal, not even excepting those apes which bear the closest resemblance to man."

The following conclusions, which Tiedemann deduces from his observations, are so important that I cannot refrain from inserting them here.*

"1. The weight of the brain of an adult male European varies between 3 lbs. 2 oz. and 4 lbs. 6 oz The brain of men who have distinguished themselves by their great talents is often very large. The brain of the celebrated Cuvier weighed 3 lbs. 11 oz. 4 dr. 40 grs. avoirdupois, or 4 lbs. 11 oz. 4 dr. 30 grs. troy weight. The brain of the celebrated surgeon Dupuytren weighed 4 lbs. 10 oz. troy weight. (Both of these eminent individuals, it ought to be remarked, died with the brain in a state of disease.) The brain of men, with feeble intellectual powers, is, on the contrary, often very small, particularly in congenital idiotismus. The brain of an idiot, fifty years old, weighed but 1 lb. 8 oz. 4 dr., and that of another, forty years of age, weighed but 1 lb. 11 oz. 4 dr.

"2. The female brain is lighter than that of the male. It varies between 2 lbs. 8 oz. and 3 lbs. 11 oz. troy. I never found a female brain that weighed 4 lbs. The brain of a girl, an idiot, sixteen years old, weighed only 1 lb. 6 oz. 1 dr. The female brain weighs, on an average, from four to eight ounces less than that of the male; and this difference is already perceptible in a new-born child.

"3. The brain arrives, on an average, at its full size towards the seventh or eighth year. Soemmering says, erroneously, that the brain does not increase after the third year. Gall and Spurzheim, on the other hand, are of opinion that the brain continues to grow till the fourteenth year. The brothers Wenzel have shewn that the brain arrives at its full growth about the seventh year. This is confirmed by Hamilton's researches."

(The reader will perceive that these statements do not exactly accord with the results of Dr. John Reid's observations. It seems probable that the data upon which Tiedemann's conclusions were founded have been too limited in number. In calculating the weight of the brain in adolescence and adult age, some allowance should be made for the greater proportion of water at the former period; the quantities of that fluid being at those ages 72 and 74 parts in 100 respectively, according to L'Héritié.)

"4. Desmoulins is of opinion that the brain decreases in old people. From this circumstance he explains the diminution of the functions of the nervous system and intellectual powers. The truth of this assertion has not as yet been determined. The brothers Wenzel, and Hamilton deny it.

"It is remarkable that the brain of a man, eighty-two years old, was very small, and weighed but 3 lbs. 2 oz. 3 dr., and the brain of a woman, about eighty years old, weighed but

* Loc. cit. p. 502.

2 lbs. 9 oz. 1 dr. I have generally found the cavity of the skull smaller in old men than in middle-aged persons. It appears to me, therefore, probable that the brain really decreases in old age, only more remarkably in some persons than in others.

" 5. There is undoubtedly a very close connection between the absolute size of the brain and the intellectual powers and functions of the mind. This is evident from the remarkable smallness of the brain in cases of congenital idiotismus, few much exceeding in weight the brain of a new-born child. Gall, Spurzheim, Haslam, Esquirol, and others have already observed this, which is also confirmed by my own researches. The brain of very talented men, on the other hand, is remarkable for its size.

" Anatomists differ very much as to the weight of the brain compared with the bulk and weight of the body; for the weight of the body varies so much, that it is impossible to determine accurately the proportion between it and the brain. The weight of an adult varies from 100 to 800 lbs., and changes both in health and when under the influence of disease, depending in great measure on nutrition. The weight of the brain, although different in adults, remains generally the same, unaltered by the increase or diminution of the body. Thin persons have, therefore, relative to the size of the body, a larger brain than stout people.

" From my researches I have drawn the following conclusions.

" 1. The brain of a new-born child is, relatively to the size of the body, the largest; the proportion is 1 : 6.

" 2. The human brain is smaller, in comparison to the body, the nearer man approaches to his full growth. In the second year the proportion of the brain to the body is as 1 : 14; in the third, 1 : 18; in the fifteenth, 1 : 24. In a full-grown man, between the age of twenty and seventy years, as 1 : 35 to 45. In lean persons the proportion is often as 1 : 22 to 27; in stout persons, as 1 : 50 to 100 and more."

(This estimate, as far as regards the early ages, differs from that of Dr. John Reid, probably owing to the difference in the number weighed.)

" 3. Although Aristotle has remarked that the female brain is absolutely smaller than the male, it is nevertheless not relatively smaller compared with the body; for the female body is, in general, lighter than that of the male. The female brain is for the most part even larger than the male, compared with the size of the body.

" The different degree of susceptibility and sensibility of the nervous system seems to depend on the relative size of the brain as compared with the body. (qu. ?) Children and young people are more susceptible, irritable, and sensitive than adults, and have a relatively larger brain. Thin persons are more susceptible than stout. In diseases which affect the nourishment of the body, the susceptibility increases as the patients grow thinner. The susceptibility and sensibility decreases, on the other hand, with persons recovering from a long illness, gradually as they regain their strength. The degree of sensibility in animals is also in proportion to the size of the brain. Mammalia and birds have a larger brain and are more susceptible than amphibious animals and fishes."*

Enough has been said to show, that in contrasting the brain of man and that of the lower animals, with reference to the much agitated question of the connexion of mental faculties and intellectual endowments with that organ, no *one* standard of comparison must be selected. We must look to absolute and relative size—we must compare the bulk of the several portions of the encephalon with each other—we must notice the size of the encephalic nerves in relation to the whole organ—and, above all, we must compare the intimate organization of brain one with the other. Unless all the features of the brains that are subjected to comparison be carefully taken into the account, erroneous conclusions will be obtained. For instance, the brain of the elephant is absolutely larger than that of man: the convolutions of the hemispheres are very highly developed, and exhibit a degree of complexity almost equal to that of the human brain. At first sight we might be led to infer a very close approximation to the human, and place the elephant very high up in the scale of cerebral developement. In comparing, however, the brain of this animal with that of the monkey, the following result is obtained. The encephalon of the elephant is above that of the monkey by the superior developement of the cerebral convolutions; it is equal to it, as regards the quadrageminal bodies, but from the general form of the brain, the length of its transverse diameter, the presence of olfactory eminences, the position of the cerebellum (uncovered by the posterior lobes), it must be placed on a level with that of the inferior Mammalia.†

Of the brain in different races of mankind.—When so much diversity is observable in the form of the cranium in different races of mankind, it seems reasonable to expect a corresponding variety in the shape and other characters of the encephalon. The external form of this latter organ will correspond with that of the cranium, and its size with the capacity of that cavity. But it is plain that as the capacity of the skull is no wise necessarily affected by its shape, so the absolute bulk of the brain need not vary, although its containing case may exhibit much variety of form. The great question for the physiologist to determine is, whether, in the various races of mankind, the brain exhibits any striking peculiarities, characteristic of one or more of them, or whether it presents no more variety of shape, size, weight, and structure than may be observed in different individuals of any one of those races.

It should be premised that actual observations of the brain of different races are few. In Europe, where hitherto anatomy has chiefly

* Tiedemann on the Brain of the Negro compared with that of the European and the Orang Otang. Phil. Trans. 1836.

† Leuret, op. cit. p. 448.

been studied, the means of instituting such inquiries on a large scale have been altogether wanting. But it may be confidently expected that the many well-educated men who now visit distant climes, accompanying our fleets and armies, will not let slip the opportunities which they possess, without contributing somewhat to the solution of so interesting a question.

Many years ago it was thought that the brain of the coloured races possessed a greater quantity of colouring matter than that of the white, and this opinion appears to have originated with J. F. Meckel, who asserted that the grey substance was of a darker hue than in the European brain, and also that the medullary substance was not so white, but yellowish grey or light-brown.* Walter, Camper, Bonn, Soemmering, have, however, amply refuted this statement.

Walter denied more particularly that part of the assertion which attributed a darker colour to the white substance. He states that it is just as white as in the European, but that the cortical substance is darker, that is, of a greyish brown colour, which he attributed to the darker colour of the blood in the Negro.†

Soemmering, with a view to decide the question, dissected three perfectly fresh Negro brains in the presence of other anatomists, Professors Weichmann, Schumlanski of Petersburgh, and Billman of Cassel, taking the very proper precaution to compare on the spot the fresh brain of an European. The result was that he could not discover either the cineritious or medullary substance to be in the least darker than in Europeans; he even thought that the colour was rather paler in the African than in the European brain.‡

It is true that Caldani and Rudolphi appear to have considered the grey substance darker in the Negro than in the European, the former having examined the brains of two Negroes, and the latter that of a Mulatto. But little dependence is to be placed on statements founded upon such a limited number of observations, and moreover it is well known that the aspect of the grey substance varies in different individuals according to the quantity of blood which it may contain.

Tiedemann affirms that the brain of the Negro does not present any material difference from that of other nations. Judging by Camper's rule, founded upon the measurement of the facial angle, which is smaller in the Negro than the European, it had been supposed that the latter was smaller. The results of a few cases in which the Negro brain was weighed do not confirm this statement. The brain of a Negro boy according to Soemmering weighed 2 lbs. 10 oz. 3 dr. avoirdupois, or 3 lbs. 6 oz. 6 dr. troy. The brain of a tall handsome Negro, about twenty years of age, weighed 2 lbs. 13 oz. 4 dr. avoidupois, or 3 lbs. 9 oz. 4 dr. troy weight. A Negro's brain, examined by Sir Astley Cooper, weighed 3 lbs. 1 oz. or 49 oz. and that of a young Negro, aged twenty-five, short and thin, examined by Tiedemann himself, weighed 2 lbs. 3 oz. 2 dr., having been a short time kept in alcohol.

Tiedemann has also contrasted the capacity of the Negro skull with those of men of the Caucasian, Mongolian, American, and Malayan races. This was done by first weighing the skull with or without the lower jaw-bone. Then the skull was weighed, having been filled with dry millet seed through the foramen magnum. Lastly, by deducting the weight of the empty skull from that of the filled one, the capacity of the cranial cavity was obtained.

In the Ethiopian race, the range of capacity was found to be, in male skulls from 54 oz. 2 dr. 33 gr. to 31 oz. 5 dr. 16 gr. troy, in thirty-eight observations, and in female skulls from 31 oz. 4 dr. to 24 oz. 7 dr. 39 gr. in three observations.

In the Caucasian race, the capacity of male skulls of European nations was found to range between 57 oz. 3 dr. 56 gr. to 32 oz. 6 dr., in seventy-seven observations, and that of male skulls of Asiatic nations from 41 oz. 5 dr. 6 gr. to 27 oz. 6 dr. 30 gr. (a Hindoo Brahmin's head), in twenty-four observations.

The male skulls of the Mongolian race exhibited a capacity from 49 oz. 1 dr. 22 gr. to 25 oz. 0 dr. 18 gr. (a native of Nootka Sound), in eighteen observations.

In the American race the capacity of the male skulls ranged between 59 oz and 26 oz. 1 dr. 44 gr. (a Toway Indian), in twenty-four observations.

And in the Malayan race it ranged from 49 oz. 1 dr. 45 gr. to 30 oz. 5 dr. in thirty-eight observations, and in five female skulls from 37 oz. 5 dr. to 19 oz. 2 dr. 49 gr. (a Lascar woman).

These researches certainly give no countenance to the doctrine which assigns the lowest place, in the chain of human varieties, to the Negro as regards cerebral developement. So far is this from being the case, that the Ethiopian race differs to a very trifling degree from the European; and, indeed, the examples of skulls of the smallest capacity are found among Asiatic natives (Hindoos) and Americans.

The following conclusions are derived by Tiedemann from his comparison of the Negro brain with that of other races.

"1. The brain of a Negro is upon the whole quite as large as that of the European and other human races.

"2. The nerves of the Negro, relatively to the size of the brain, are not thicker than those of Europeans, as Soemmering and his followers have said.

"3. The outward form of the spinal cord, medulla oblongata, the cerebellum and cerebrum of the Negro show no important difference from that of the European.

"4. The Negro brain does not resemble that of

* De la diversité de couleur dans la substance medullaire de Negres, Hist. de l'Acad. de Berlin, 1753. Du Cerveau des Negres, ibid. 1757, quoted in Tiedemann's paper.

† Epistola Anatomica ad W. Hunterum de venis oculi. Berolin. 1778.

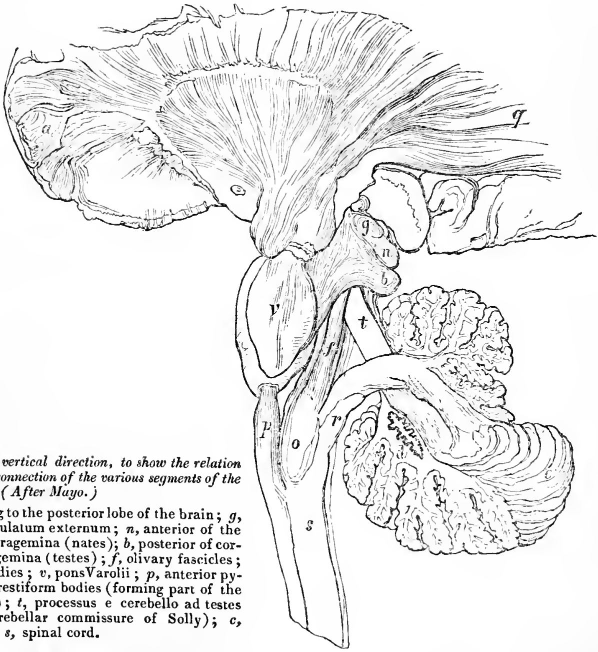
‡ Vom Korperlichen Unterschied des Negers, p. 18.

the orang otang more than the European brain does, except in the more symmetrical distribution of the gyri and sulci. It is not even certain that this is always the case. We cannot therefore coincide with the opinion of many naturalists, who say that the Negro has more resemblance to apes than Europeans in reference to the brain and nervous system. It is true that many ugly and degenerate Negro tribes *on the coast* show some similarity in their outward form and inward structure to the ape; for instance, in the greater size of the bones of the face, the projecting alveoli and teeth, the prominent cheek-bones, the recession of the chin, the flat form of the nose-bones, the projecting and strong lower jaw, the position of the foramen occipitale magnum, the relative greater length of the ossa humeri and the bones of the foramen, the flat foot, and in the length, breadth, shape, and position of the os calcis. * * * These points certainly distinguish many Negro tribes from the Europeans, but they are not common to all the Negroes of the interior of Africa, the greater number of which are well made, and have handsome features."*

A series of researches so extensive and conducted with so much care, (although the actual comparison of the brains themselves is yet wanting,) cannot allow a doubt to arise as to the conclusion which ought properly to flow from them. It would appear from them that no very marked differences exist between the brains of any of the classes of mankind—that the same relative inferiority of women to men is universally met with—and that a very diminutive state of brain may be, when not an accompaniment of idiotcy, either a part of a frame originally very small in stature, or a degenerate condition consequent upon a life of the lowest barbarism, under every possible physical impediment to the developement of bodily vigour, wholly deprived of moral or intellectual culture, a state which becomes more and more degenerate in each succeeding generation, or, lastly, the effect of the mechanical compression to which many tribes subject the crania of their offspring in early infancy.

In proceeding to the examination of the human encephalon, it seems expedient to premise a few observations on the method which it is most advisable to adopt for this purpose.

Fig. 380.



Section in the vertical direction, to show the relation and mode of connection of the various segments of the encephalon. (After Mayo.)

g, fibres passing to the posterior lobe of the brain; *g*, corpus geniculatum externum; *n*, anterior of the corpora quadragemina (nates); *b*, posterior of corpora quadragemina (testes); *f*, olivary fascicles; *o*, olivary bodies; *v*, pons Varolii; *p*, anterior pyramids; *r*, restiform bodies (forming part of the crus cerebri); *t*, processus e cerebello ad testes (cerebro-cerebellar commissure of Solly); *c*, cerebellum; *s*, spinal cord.

The inferior limit of the encephalon is the plane of the occipital foramen. In examining

* The remaining observations of Tiedemann on the intellectual condition of the Negro merit attentive perusal. See also Prichard on the Physical History of Mankind, vol. i. p. 197, and vol. ii. p. 346.

that great nervous mass which is situate above this plane, it will be obvious, even to the most superficial observer, that it admits of a convenient subdivision into certain great segments, each of which, although extensively connected with the neighbouring ones, may yet be capable of acting as an independent centre, and, in short, possesses the anatomical as well as physiological properties of a ganglion. And on a more minute investigation the number of gangliform segments will be found to be greater than the observation of the mere surface of the encephalon would lead us to conclude. The subdivision, however, which it is most convenient for the purpose of description to adopt, is that already stated at page 650, into, 1, *the medulla oblongata*, which is immediately continuous inferiorly with the spinal cord. This segment has certain characters of structure which decidedly indicate its ganglionic nature; several nerves of considerable size and of great physiological importance are implanted in it, and its external anatomy very clearly indicates its distinctness from the spinal cord inferiorly and from the other encephalic segments above, of which that next in order proceeding from below upwards, is, 2, the *mesocephale*. To this mass, so called because of its intermediate position between the other segments, the term *isthmus* has been also very appropriately applied, as it is the connecting link between all the encephalic segments. Inferior and posterior to it is placed, 3, the *cerebellum*, which has very intimate relations to the medulla oblongata as well as to the segment last described, but much less extensive ones to that which forms by far the largest proportion of the encephalon, namely, 4, the *cerebrum*, which therefore occupies the principal portion of the cranial cavity.

The distinction between these different segments is very obvious on an examination of the surfaces of the brain, which indeed ought to be the first step to be taken by the anatomist. To discover how they are connected to each other and to the spinal cord, how the corresponding portions on opposite sides of the mesial plane are associated together, what fibres are common to all the segments, and what peculiar to some, and, lastly, how the grey matter is related to the white,—these are the chief objects to be attained in the dissection of the brain. No one method of dissection will suffice for this purpose. The anatomist should first make himself familiar with the simple topographical anatomy of the brain, that is, with all those parts in it which possess such characters of form or structure as may entitle them to be regarded as distinct and deserving of separate description, and have obtained for them a special appellation. The form, size, general structure, and relations of these parts should be carefully noted. And this method of examination is equally applicable to the dissection of each segment of the encephalon. But the most convenient way in which it can be conducted for ordinary practical purposes, is to commence with the cerebral hemispheres, and having studied their general structure as displayed on a horizontal section, to examine the extent and connections of the fibres which connect the right and left hemispheres with each other (the corpus callosum); then to open the ventricles, examine their shape and extent, and note the various particulars connected with the numerous parts which are brought into view by exposing those cavities. The dissector may next observe how certain of the parts concealed by the lateral ventricles are connected with the mesocephale (the optic thalami for instance), and, having been already acquainted with the various prominences which are seen upon the surface of the latter, he may by vertical, or transverse, or horizontal sections, investigate the manner in which the white matter of this segment connects itself with that of the neighbouring ones. In examining the cerebellum, the larger fissures afford sufficient indication for a convenient subdivision of the organ, and by horizontal or vertical sections at various parts of it the connexion of the grey and white matter may be displayed, and of the latter to the mesocephale and medulla oblongata. The medulla oblongata has upon its surface various lines or fissures which denote the proper limits of its constituent columns, and which will be sufficient guide to the dissector in tracing the extent and connexions of each. Transverse and longitudinal sections also afford useful information respecting the structure of this segment of the encephalon and the relations of its parts.

Such is the mode of dissection from above downwards, against which it has been greatly the fashion of late years to declaim with much vehemence. But, however the advocates of a particular theory may object, there can be no doubt that this method is by far the most useful for all practical purposes. It enables the anatomist, without difficulty, to study the prominent parts or landmarks (so to speak) of the brain, without a knowledge of which it is in vain to attempt any other mode of dissection. And for pathological investigations it is the only method which can be conveniently adopted. It is plain, therefore, that all who are desirous of becoming acquainted with the anatomy of this organ should begin by making dissections in this way. An additional advantage is found, in this mode of investigation, from its great applicability to the dissection of the brains of the lower animals, of the Mammalia and Birds especially, for the purpose of comparing them with the brain of the human subject.

The method of our celebrated countryman Willis was very much the same as that above described. He removed the membranes from the posterior lobes of the hemispheres, and thus separated the latter from the subjacent parts, and by raising them as far forwards as possible he was enabled to observe the connections of the cerebral hemispheres with the mesocephale, and the attachments of the fornix behind. He also must have studied the substance of the hemisphere by horizontal section. By then dividing the posterior parts of the hemispheres horizontally along the plane of the corpora striata, he raised a large flap consisting of the upper part of the hemispheres, with the intervening corpus callosum and the adherent fornix; and thus were exposed the inferior surface of the latter, and the cavities of the three ventricles, the fourth being shewn by a vertical section of the cerebellum on the median plane, and by the separation of the segments thus made. This is an admirable section to display the connection of the hemispheres with what Willis described as the medulla oblongata, namely, in the words of his translator, "all that substance which reaches from the inmost cavity of the callous body and conjuncture in the basis of the head to the hole of the hinder part of the head, where the same substance being yet further continued ends in the spinal marrow." The fourth, seventh, and eighth plates in Willis's work display this mode of dissection.*

The modern researches of Reil, Gall and Spurzheim, and others, directed attention more particularly to the physiological anatomy of the brain. Their principal object was to discover the mode of connexion of the several segments of the cord with each other, and of the whole encephalon with the spinal cord. And their method of dissection consisted in tracing the course of the fibres chiefly from below upwards. Reil found it necessary to harden the brain in alcohol, in order to give it such firmness as would enable him to tear portions of it in the direction of its fibres, and thus to make these latter conspicuous. There can be no doubt that layers of the brain will separate most readily when torn in the direction of their fibres; and thus this mode of preparation becomes of great importance to the anatomist, as he can thereby determine easily the direction of those fibres which form the principal portion of the part under examination. It will not, however, suffice to display the direction of all the fibres, nor indeed is any mode of preparation adequate for that purpose, which can only be accomplished by extensive and patient microscopic investigation.*

The great advantage of pursuing the dissection in the direction from below upwards consists in this, that we proceed from the more simple to the more complex. The problem which the anatomist has to solve is, Given certain columns or bundles of fibres in the medulla oblongata, to determine how they connect themselves with the other segments of the brain. But it is obvious that without some knowledge of the topography of the other more complicated parts of the encephalon, the dissector would have considerable difficulty in pursuing his researches. Nor must he content himself with the solution of this fundamental question; he is to explore for other fibres in these segments besides those which connect them with the medulla oblongata, and he has to ascertain how they comport themselves, whether as forming an integrant portion of the segment in which they are found, or serving to connect it with one or more of the others.

Although we are mainly indebted to modern anatomists for following out more completely this method of dissection, it cannot be denied that such men as Willis, Vieussens, and Malpighi were quite alive to the importance of examining the fibres of the brain, with a view to the physiological action of its different parts. No one can peruse Willis's admirable account of the brain without perceiving how completely he unites structure and function, and with what

* Thomæ Willis, Cerebri anatome, nervorumque descriptio et usus, in Opera Omnia, Amsterdam, 1682, cap. xiii. Also an English edition by S. Pordage, London, 1684. The following extract gives the description of Willis's dissection in his own words. "Ut cerebri ita proprie dicti anatome rite celebretur, haud vulgari sectionis modo procedendum esse existimo. Verum ubi totius ἐγκεφάλου calvaria exempti compages coram sistitur, imprimis posterior cerebri limbus, ubi cerebello ac medullæ oblongatæ connectitur, membranis undique discissis aut avulsis, a cohæsione cum partibus subjectis (quantum fieri potest) liberetur; tunc facile constabit quod cerebri substantia corporibus istis haudquaquam unitur, verum per se, nisi quod membranarum nexu superficie tenus conjungitur ab iis omnino libera ac independens fuerit: quinetiam hæc cerebri puppis a vicinis partibus eo ritu divisa, si anterius reclinetur, medullæ oblongatæ crura, prorsus nuda, ac a cerebro et cerebello (nisi in quibus locis hæc illi appenduntur) omnino distincta apparebunt. * * * * * * * * * * * * * * * * Interioris cerebri recessus adhuc clarius patebunt, si limbus ejus a medullæ oblongatæ cohæsione, quantum fieri potest, ex omni parte separatus et elevatus, ad latera ejusdem medullæ, quibus juxta corpora striata unitur, paulo ulterius per substantiam suam secetur, simulque fornix juxta radices discissus una cum cerebro reflectatur, tunc enim cerebri compages penitus elevari, antrorsum reflecti, ac in planum explicari potest, ita ut corporis callosi in aream latam expansi interior superficies tota conspici et tractari possit. Ubi, præter medullarem et nitidissimam illius substantiam, observare est plures lineas albas paralelas quæ cerebri dissepimentum rectis angulis secant; quasi essent tractus quidam, sui vestigia, in quibus spiritus animales ab uno cerebri hæmispherio in alterum migrant resiliuntque." Op. cit. cap. i. p. 5, 6.

* Reil's methods of preparing the brain are best described in his own words: "Of the methods which I have employed in preparing brains, those contained in the following directions answered best. 1. Let the brain be hardened in alcohol, and then placed in a solution either of carbonated or pure alkali, in the latter two days, in the former for a longer period, and then again hardened in alcohol if thus rendered too soft. The advantage of this method is, that the fasciculi of nervous matter are more readily separable, and the brown matter more distinguishable from the white than after simple maceration in alcohol; the grey matter is rendered by the alkali of a blacker grey, and assumes the consistence of jelly. 2. Let the brain be macerated in alcohol, in which pure or carbonated potass or ammonia has been previously dissolved; the contraction of the brain is lessened by this process. 3. Let the brain be macerated in alcohol from six to eight days, and then its superficial dissection commenced, and the separation of the deeper parts continued, as the fluid, in which the brain is kept immersed, penetrates its substance. This method appears to me better than the preceding, and would very likely be improved if the alcohol were rendered alkaline. The fibres in a brain, thus prepared, are more tenacious than otherwise, and the deeper parts are sooner exposed to the influence of the alcohol."—Mayo's translation of Reil's Eighth Essay, in the former's Anat. and Phys. Commentaries, p. ii. p. 50.

ingenuity he ascribes the passage of the nervous force (under the name of animal spirits) from one part to another, to the anatomical relations of those parts, and the direction of the constituent fibres. And, indeed, we may find in the writings of this great man the germs of many a theory which, in our own times, has been brought forward with a more plausible aspect, disencumbered of the quaint phraseology and superabundant metaphor so common in his day. I shall quote one remarkable instance as very much in point. Speaking of the fourth pair of nerves as connected with the corpora quadragemina, he says: "Concerning these little nerves it is observed, that when (although) many others proceed from the sides or the basis of the oblong marrow, these arise from the aforesaid Prominences in the bunching forth at the top (nates and testes). The reason of which, if I be not mistaken, is this,—we have affirmed that these prominences do receive and communicate to the brain the natural instinct delivered from the heart and bowels to the cerebel; and on the other side, or back again, do transfer towards the Præcordia, by the mediation of the cerebel, the forces of the passions or affections received from the brain; but in either action the motion of the eyes is affected with a certain manifest sympathy. For if pain, want, or any other signal trouble afflicts the viscera or the præcordia, a dejected and cast-down aspect of the eyes will declare the sense of its trouble: when on the contrary, in joy, or any pleasant affection of the præcordia or viscera, the eyes are made lively and sparkle again. In like manner the eyes do so clearly show the affections of the mind, as sadness, anger, hatred, love, and other perturbations, that those who are affected, though they should dissemble, cannot hide the feeling and intimate conceptions of the mind. Without doubt these so happen because the animal spirits tending this way and that way in this deviating place between the brain and the præcordia, do at once strike those nerves as the strings of a harp. Wherefore, from this kind of conjecture, which we have made concerning the use of these nerves, we have called them *Pathetical*, although indeed other nerves may deserve the same name."*

Malpighi and Vieussens were well acquainted with the fibrous structure of the brain, and appear to have had very correct notions as to the general direction which they assume, and the parts which they serve to connect to each other. The former describes the fibres of the brain and cerebellum as taking their origin from the trough of the spinal marrow contained within the cranium (*medulla oblongata*); "for they ramify from four reflected crura of this medulla in all directions, until they end by their branched extremities in the cortex." Vieussens states that the medullary substance is composed of innumerable fibrils connected together and arranged into various fasciculi, which become very obvious when it is boiled in oil.†

The great merit of Reil, Gall and Spurzheim, and their followers in later years, consists in their having followed out with great diligence the coarser anatomy of those fibres, and determined many important and undeniable truths. But in the statements of all anatomists, who avail themselves of no other aid than that which the naked eye affords, there is much that must necessarily be uncertain or doubtful, nor is there any other mode of removing these uncertainties but by the successful application of microscopical analysis to the whole cerebral structure.

Of the surface of the encephalon—We now proceed to examine the various points worthy of notice in the superficial anatomy of the encephalon.

The shape of the brain is determined by that of the cerebral hemispheres. A line drawn around the surface of the latter, so as to enclose them, would describe an oval, the smaller extremity of which is directed forwards.

The superior and lateral surfaces of the encephalon are convex, and have a smooth appearance from the visceral layer of the arachnoid being extended over them, adhering to the subjacent pia mater. When the membranes have been removed, the convoluted character of these surfaces, previously seen through them, becomes very manifest, as will be more particularly described by-and-bye. The longitudinal and transverse diameters of these surfaces correspond to those of the cranial cavity.

The superior surface is divided along the median plane into two equal and in a great degree symmetrical portions by a fissure which passes vertically between them and receives the great falciform process of the dura mater. In front and behind, this fissure completely divides the central lobes. In the latter situation, the tentorium cerebelli is seen at the bottom of it when the hemispheres are separated, if the encephalon be in situ; if it have been removed, however, the superior surface of the cerebellum forms the floor of the fissure. In the middle the fissure is interrupted by a horizontal lamina of white fibres, which is called the *corpus callosum*, the great commissure of the cerebral hemispheres.

The inferior surface of the encephalon also, called commonly the *base of the brain*, presents many points worthy the attention of the anatomist.

It is not all upon one level: in this respect it corresponds with the disposition of the base of the skull. We find, indeed, three segments, each on a different plane, and corresponding to each of the three fossæ of the cranium. This is best observed by examining a vertical section of the head, the brain being retained in its situation, or by removing the wall of the cranium on one side quite down to its inferior surface.

The anterior segment, and that which is on

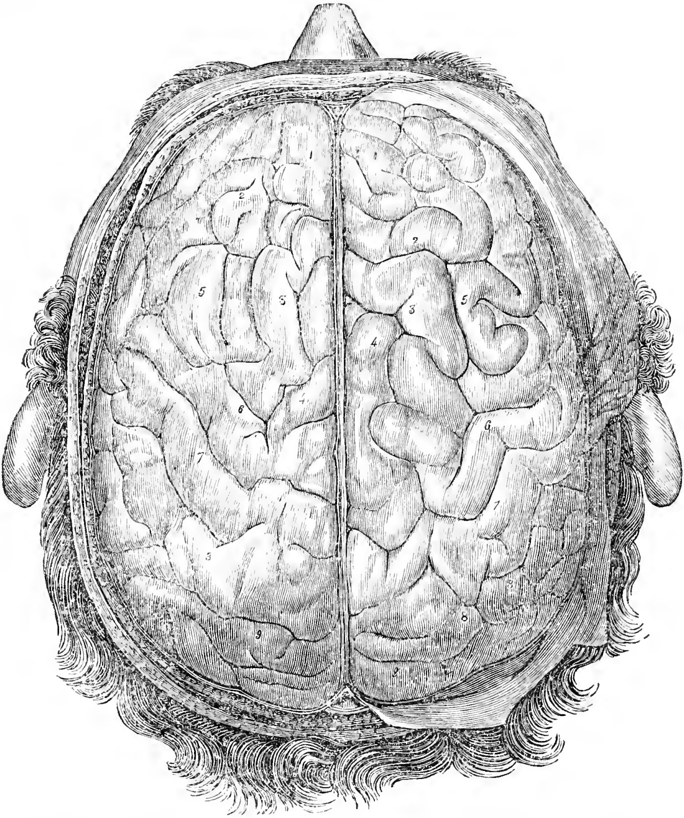
† Malpighi, Exercitatio Epistolica de Cerebro, 1664. Vieussens, Neurographia Universalis, lib. i. cap. x. See the whole passages quoted in Dr. Gordon's Observations on the Structure of the Brain. Edin. 1817, p. 21.

Fig. 381.



The superior and part of the lateral surfaces of the encephalon, exposed by the removal of the calvaria. The falx cerebri is seen in the longitudinal fissure. The figures on the convolutions indicate those of opposite sides which present some degree of symmetrical character. They will be referred to further on in the description of the hemispheres of the brain.

the highest level, corresponds to the anterior fossa of the cranium. It rests, therefore, upon the roofs of the orbits, and its surface is on each side slightly concave to adapt it to the form of its resting-place. The continuation of the anterior median fissure separates its right and left portion, and the attachment of the falx to the crista galli of the ethmoid makes the distinction more complete. In a distinct sulcus, parallel to and immediately on each side of the longitudinal fissure, we find the olfactory process or nerve. This segment forms the inferior surface of what anatomists commonly designate as the anterior lobes of the brain. It presents the convoluted appearance which is conspicuous on the proper cerebral surface every where. A curved fissure of considerable depth, called the *fissure of Sylvius*, is the posterior limit of each anterior lobe.

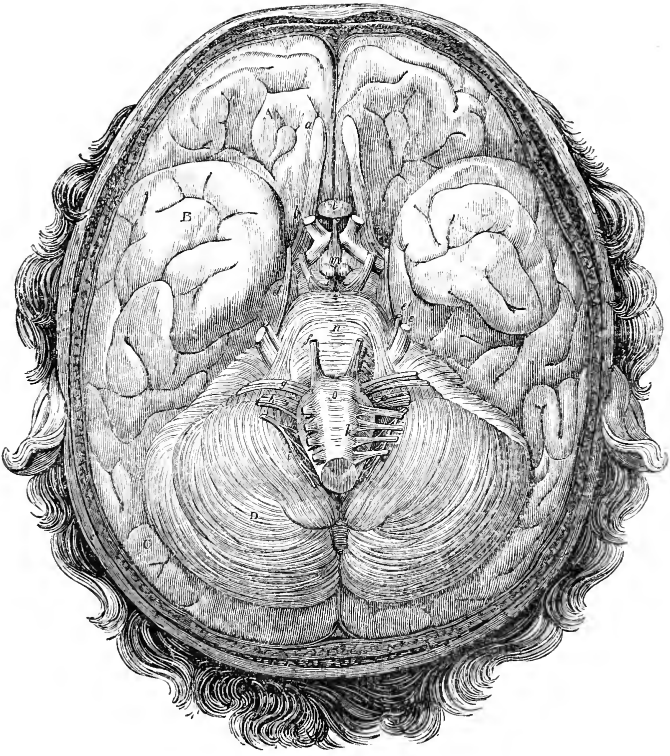
The fissure of Sylvius corresponds on each side to the posterior concave edge of the lesser ala of the sphenoid bone, which is received into it. It may be traced from within, commencing at a triangular flat surface *(locus perforatus anticus)*, which corresponds to the posterior extremity of each olfactory process. From this situation it proceeds outwards and curves backwards and a little upwards; its convexity is therefore directed forwards. Towards the lateral surface of the brain it becomes continuous with the fissures of neighbouring convolutions.

The fissure of Sylvius is of considerable depth, especially at its internal extremity, and, like all the fissures of the brain, large or small, is lined by the pia mater. We notice here a large interval between the arachnoid and pia mater, in which a considerable accumulation of the cerebro-spinal fluid takes place, communicating with the anterior conflux of that fluid. In this space runs the middle artery of the brain, giving off its branches to the sides and floor of the fissure. When the convolutions which bound the fissure are separated, a variable number of small convolutions is found, projected from its floor as an insulated lobe, which is enclosed by a bifurcation of the fissure. This lobe constitutes the island *(insel)* of Reil.

The *middle* segment which lies immediately behind the Sylvian fissure, is on a plane much lower than the anterior, and corresponds on either side to the deep and hollow median fossa of the cranium. It consists of two lateral very convex lobes, commonly known as the *middle lobes of the brain,* which are separated from each other by a deep depression. These lobes, which are very accurately limited in front by the fissure, have no exact boundary behind, but pass off very gradually into the *posterior lobes* of the hemispheres, as may be seen by raising up the cerebellum.

The transition from the middle to the posterior lobe of the hemisphere is only indicated by the different character of the inferior surface of the hemisphere, the former being convex, the latter concave. The subdivision, indeed, of the cerebral hemisphere into middle and posterior lobes is purely conventional, and I agree with Cruveilhier that it ought to be discarded, for it has no foundation in the anatomy

Fig. 382.



Base of encephalon viewed from below.

A, anterior lobe; B, middle lobe; C, posterior lobe; D, cerebellum; *a*, olfactory nerves; *b*, optic nerves; *c*, third pair of nerves; *d*, fourth pair of ditto; *e*, fifth pair—portio major; *e'*, fifth pair—portio minor; *f*, sixth pair; *g*, seventh pair; *h*, filaments of origin of the glosso-pharyngeal and vagus; *i*, spinal accessory nerve; *k*, ninth nerve; *l*, pituitary body and process proceeding from the tuber cinereum; *m*, mamillary bodies; *n*, pons Varolii; *o*, medulla oblongata.

of the parts. The whole of that portion of the cerebral hemisphere which is situate behind the Sylvian fissure should be called the posterior lobe.

The hollow space between the middle lobes of the brain corresponds to the principal anterior reservoir of subarachnoid fluid. It is situate immediately above the Sella Turcica, and, indeed, the brain is, as it were, tied to the pituitary body, which is firmly lodged in this excavation of the sphenoid bone, by a funnel-shaped hollow process of nervous matter, called *pituitary process* or *tube*, (*m, l, fig.* 382), which, enveloped in a sheath of arachnoid membrane, is inserted into it by its small extremity. This space communicates with the anterior fissure in the middle, and with the Sylvian fissure on either side.

Commencing at the anterior fissure and passing backwards, we notice the following parts, to see which clearly it is necessary that the adherent pia mater and the arachnoid should have been previously carefully dissected away. The anterior fissure is limited by the anterior fold or reflection of the corpus callosum: behind this we find a thin layer of a lightish grey matter, which, like a triangular plate, seems to stop up the third ventricle at its inferior surface. This, indeed, which is called *tuber cinereum*, constitutes a principal part of the floor of that ventricle. The pituitary process is continuous with and is probably an extension of it. A probe introduced into the cut extremity of this process will be found to pass readily into the third ventricle.

Immediately in front of the pituitary process, the union of two white bands, which form lateral boundaries to a large portion of the tuber cinereum, *the optic tracts*, takes place along the middle line. This forms the *commissure* of the optic nerves, from which these nerves diverge. Behind the pituitary process the tuber cinereum extends back to two small pisiform bodies of an extremely white colour on their surface, *corpora mamillaria* or *albicantia* (*m, fig.* 382). These, we shall see by-and-bye, are connected with one of the most important of the cerebral commissures, namely, the *fornix*.

Behind the mamillary bodies we find a deep depression into which the pia mater sinks, carrying with it very numerous bloodvessels. This depression lies between two thick processes of fibrous matter, which, traced from below, pass upwards and outwards, expanding as they advance, and upon which each hemisphere is placed (to use Reil's simile) like a mushroom on its stalk. These are the *crura cerebri*, the peduncles of the cerebral hemispheres. The depression above described, which separates them, is the *intercrural* or *interpeduncular* space. When the pia mater has been removed from it, its surface appears cribriform from the perforations of the numerous minute vessels which penetrate it; it has been named by Vicq d'Azyr *substantia perforata media*. The nervous matter which forms the floor of this space has a greyish hue, and connects the crura to each other, like a bridge, whence the designation *pons Tarini*. At the interpeduncular space we see the third pair of nerves emerging from their connexion with the crura cerebri.

The inner margin of each middle lobe of the brain is separated from the corresponding crus cerebri by a fissure which passes from behind forwards, and terminates in the fissure of Sylvius. If this fissure be followed backwards, it will be found to become continuous with a transverse fissure which separates the cerebrum from the cerebellum, and corresponds to the posterior edge of the corpus callosum. A continuity is thus established between the lateral and the transverse fissures, whence results one great fissure of semicircular form, the concavity of which is directed forwards. This is the *great cerebral fissure* of Bichat, or the great *transverse* or *horizontal fissure* (Cruveilhier.) It may be described as commencing at the fissure of Sylvius on one side, turning round the opposite cerebral peduncle, and ending at the opposite Sylvian fissure. The anterior and lateral portions of this fissure have already been noticed as the situations at which the pia mater enters the brain to form the choroid plexuses of the lateral ventricles. And it may be remarked here, how freely the subarachnoid fluid may pass along this fissure from before backwards. Parallel to this fissure we find the fourth pair of nerves as it passes to its point of exit from the cranium.

Not the least interesting and important of the objects presented at this central portion of the base of the brain is that remarkable arterial anastomosis, called the *circle of Willis*. This will be more particularly described by-and-bye; but it may be stated here, that the anterior bifurcation of the basilar artery is immediately behind the interpeduncular space, on each side of which the posterior cerebral artery passes for a short distance. The posterior communicating artery is parallel to the inner edge of the middle lobe; the subdivision of the carotid corresponds to the commencement of the Sylvian fissure; and the anterior communicating artery is at right angles with the longitudinal fissure immediately behind the anterior reflection of the corpus callosum. This anastomosis of arteries is bathed in the liquid which occupies the subarachnoid space in this situation.

The tentorium cerebelli is situate on a plane a little beneath that of the middle segment of the base of the encephalon just described. It forms a septum between the posterior lobes of the cerebral hemispheres, which are continuous with the middle segment, and the posterior segment of the encephalon, which we now proceed to describe.

The posterior segment, as occupying the posterior fossa of the cranium, is on a level considerably below that of the middle segment. The parts which are deserving of more particular notice here, are, proceeding from before, the pons Varolii (*n, fig.* 382), the inferior and anterior surface of the mesocephale, which is situate immediately behind the interpeduncular space, the crura cerebri appearing to emerge just above its anterior border. From its posterior edge the medulla oblongata (*o*) extends downwards, and a little backwards. As the brain rests on the upper surface of its hemispheres with its base upwards, the medulla oblongata is seen to occupy a notch or depression between the hemispheres of the cerebellum. The fibres of the pons Varolii are seen passing outwards and backwards into each hemisphere of the cerebellum, forming the inferior layer of each crus cerebelli. On each side of the medulla oblongata is the inferior convex surface of each hemisphere of the cerebellum marked by its fissures and laminæ. The basilar artery passes in a groove along the middle of the pons from before backwards. The fifth nerve emerges from the crus cerebelli, the sixth immediately below the posterior margin of the pons, and the seventh, eighth, and ninth nerves are seen springing from each side of the medulla by a series of fascicles similar to those which form the roots of the spinal nerves.

Of the dissection of the brain from above downwards.—It will facilitate our subsequent descriptions, if, previous to examining the several segments of the encephalon in detail, I give a rapid sketch of the dissection of the brain according to the *topographical* method, proceeding from above downwards.

This dissection is commenced by making a horizontal section of one hemisphere, a little above the level of the corpus callosum. The surface, which is thus exposed, has in shape the character of a demi-oval. It is chiefly composed of white substance, which occupies the centre of the space, bounded by a wavy border of grey matter. Anatomists designate it *centrum ovale minus*. We find this is a convenient section on which to study the anatomy of the convolutions, and to give some idea of the composition of that portion of the hemispheres of the brain which is situate above the ventricles. On making a similar section of the other hemisphere at the same level, a similar surface is exposed, and the conjunction of both constitutes what Vieussens denominated the *centrum ovale majus*.

By separating the hemispheres slightly, after this section, the horizontal portion of the corpus callosum is well displayed. The continuity of its transverse fibres with the white substance of the hemispheres may be traced; and by following its anterior and posterior reflections they will be found to connect the hemispheres at their inferior as well as their superior parts. The corpus callosum, when examined in its full extent, exhibits somewhat of a vaulted shape, and is found to enter largely into the formation of the roof of the lateral ventricles.

We notice some remarkable longitudinal fibres, passing along the middle of the corpus callosum, varying greatly in developement in different brains. These consist of two bundles placed in juxta-position, but easily separable. We may trace them throughout the whole length of the corpus callosum. They cut the transverse fibres at right angles, and may be readily dissected up from them. They seem to tie the transverse fibres together, and are probably commissural. They form what has been improperly called *the raphé* of the corpus callosum, more correctly *the longitudinal tracts* (Vicq d'Azyr).

By scraping away the white substance, on each side of the corpus callosum, the lateral ventricles may be opened. If this be done with great care, a considerable portion of the membrane that lines the interior of each ventricle may be exposed, but such is its great delicacy that a very slight force ruptures it. When there is fluid in the ventricles, this membrane may be more easily demonstrated from its floating upon the fluid. The place at which the ventricles may be most certainly opened without the risk of injuring any of the parts contained within them, is about the eighth of an inch external to the blending of the fibres of the corpus callosum with the white substance of the centrum ovale. With the handle of a knife the fibrous matter which forms the roof of the ventricle may be torn through in the antero-posterior direction, and the cavity thereby exposed.

Each lateral ventricle consists of a horizontal and a descending portion. The former resembles in shape an inverted italic *S*. Its *anterior* extremity, or *cornu*, is directed outwards; the *posterior* turns inwards towards that of the opposite side. The *descending cornu* passes downwards, forwards, and inwards in a curved course with the concavity forwards and inwards, and terminates at the fissure of Sylvius. The first has been appropriately designated the *frontal* ventricle, the second the *occipital*, and the third the *sphenoidal*, from their relations to the bones after which they have been respectively named. The posterior cornu is also named the *digital*, or *ancyroid* cavity.

The anterior cornua of the lateral ventricles are separated from each other by a vertical septum situated on the median plane, very thin and transparent, the *septum lucidum*. This may be easily demonstrated on a vertical section of the brain, made a little to one side of the mesial plane, or if both lateral ventricles have been opened, by supporting the corpus callosum on each side with the handle of a knife, by which means the septum is stretched, and its extent and connections may be more readily determined. The septum is of a triangular form with curvilinear base, which is directed forwards, and fits into the anterior reflection of the corpus callosum. Posteriorly it fits in between the corpus callosum and the anterior extremity of the horizontal portion of the fornix.

The septum lucidum, although so extremely delicate and transparent, is very obviously composed of two layers, which enclose a space or cavity called the *fifth ventricle*. This may be shewn by dividing the septum horizontally from behind forwards. Each of these laminæ consists, as may be easily observed by examining the margin of the section, of four layers: the outer one is derived from the lining membrane of the ventricles; immediately within this is a layer of a pale greyish matter continuous with a similar layer which covers the optic thalami and the internal surface of the third ventricle, consisting of clear nucleus-like particles homogeneous in texture; a third layer is composed of white or fibrous matter; and a fourth consists of an extremely delicate membrane, probably covered by ciliated epithelium, which lines the internal surface of the fifth ventricle.

The fifth ventricle is closed at every point, and has, therefore, no communication with the lateral or other ventricles. It has been regarded by some as resulting merely from the artificial separation of the laminæ of the septum lucidum. And it seems unlikely that in life, during health, the surface of these laminæ should be otherwise than in contact, lubricated, however, by a slight moisture exhaled by the membrane. In a few rare cases fluid has been known to accumulate in this cavity.

In the fifth month of uterine life, according to Tiedemann, this ventricle communicates with the third through a small space, situate between the anterior pillars of the fornix and above the anterior commissure, and indeed it may be looked upon as a portion of the latter ventricle closed off by the formation of the fornix and septum lucidum.

The following parts are to be noticed in each lateral ventricle:—1. In the anterior horn, the *corpus striatum*, a pear-shaped eminence, the obtuse extremity of which is directed forwards and inwards. Posteriorly this body is apparently prolonged backwards into the inferior cornu of the lateral ventricle by a long tapering process which terminates there. 2. Internal and posterior to the corpus striatum is the *optic thalamus*, a gangliform body of a greyish colour, but considerably paler than that last named. 3. These two bodies are separated from each other by a superficial groove, in which lies a delicate band of fibrous matter, the *tænia semicircularis*, which is covered by a lamina of horny-looking matter, *lamina cornea*, the formation of which is attributed by some to a thickening of the lining membrane of the ventricle along this groove.

The choroid plexus in a great degree covers and conceals from view the optic thalamus. It passes up from the descending cornu, and just behind the septum lucidum and anterior pillars of the fornix turns inwards to unite with its fellow of the opposite side. On its inner side it is slightly overlapped by the thin margin of the horizontal portion of the fornix.

In the posterior horn we observe, on its internal wall, a projection inwards of one of the convolutions to which the name *hippocampus minor*, or *ergot*, has been given. It is an internal convolution, covered by a layer of fibrous matter derived from the fornix. It is traversed by a deep sulcus, which may be exposed by cutting it across.

The descending horn contains a remarkable prominence, the *hippocampus major*, (also called *cornu Ammonis*,) which projects into it from its inferior wall, and follows the curve of the horn. It likewise may be regarded as an internal convolution, and is covered by a layer of fibrous matter derived from the fornix, which overlaps the concavity of the hippocampus by a thin margin, called *corpus fimbriatum*. Beneath this is a peculiar disposition of grey matter connected with the hippocampus, to which the name *fascia dentata* has been given. The commencement of the choroid plexus is found in this horn.

The anterior extremity of the descending horn of the lateral ventricle corresponds with the posterior extremity of the fissure of Sylvius. It is closed, not by nervous matter, but simply by the reflection of the membrane of the ventricle on the choroid plexus. This is the only provision against the escape of fluid from the ventricle. It seems highly probable, as we have already intimated, that there may be a communication at this situation, as well as at the fourth ventricle, between the fluid of the ventricles and that of the sub-arachnoid cavity by endosmose and exosmose. And the delicacy of the barrier which is opposed to the escape of fluid from the ventricle explains the occurrence of sanguineous effusions at the base of the brain from the rupture of vessels within the ventricle.

Postponing the more minute description of the parts found in the lateral ventricle, as above enumerated, we proceed with the examination of those which are brought into view beneath the corpus callosum.

The corpus callosum, which we have seen to consist of bundles of transverse fibres, passes directly from one hemisphere to the other. At its anterior and posterior extremity it is folded downwards, so as to connect those parts of the hemispheres which lie on a plane inferior to the lateral ventricles. Its anterior reflected portion, therefore, contributes to form the floor of the anterior horn, and the posterior one mingles with the fibres of the inner wall of the posterior horn. This disposition of the corpus callosum is best seen on a vertical section of the brain, which shows the vaulted form of this body. The greater abruptness of reflection of its posterior than of its anterior extremity, however, impairs in a great degree this character.

Of the fornix.—We have seen that the anterior reflection of the corpus callosum is occupied along the median plane by the vertical *septum lucidum*. This septum rests posteriorly upon the apex of a horizontal stratum of fibrous matter which forms part of a series of fibres called the *Fornix* or *Vault*. It is inconvenient to change names which have long been in use, more especially when there is no very certain scientific foundation for the adoption of a new one; otherwise the term *antero-posterior commissure*, which is suggested by the direction and the extensive connection of its fibres, might be appropriately assigned to it.

The principal portion or body of the fornix lies immediately beneath the three posterior fourths of the corpus callosum. By cutting this body across just at the posterior extremity of the septum lucidum, and dissecting the anterior segment forwards, and the posterior one backwards, its horizontal portion is exposed. In this dissection it is found that the latter portion of the corpus callosum is intimately adherent to the fornix. So close indeed is this adhesion that the separation is always attended with injury to the fornix. The deep-seated fibres of the corpus callosum seem to unite the lateral halves of the fornix.

The horizontal portion of the fornix, as exposed by this dissection, has the form of a triangle, the apex of which is directed forwards, and corresponds to the posterior angle of the septum lucidum. Its base is situate behind, and is enclosed by the posterior folded portion of the corpus callosum. The apex is prolonged into two rounded cords of fibrous matter, which pass downwards and outwards, in a somewhat curved course, with their convexity directed forwards. These are the *anterior pillars* of the fornix. As they descend, they diverge from each other. We can follow them down to the base of the brain, where they form two small tubercles, the *corpora mamillaria*, from which fibres are continued upwards and outwards into the substance of the optic thalamus.

The *posterior* pillars of the fornix are expansions of fibrous matter which are continuous with the angles of the base of its horizontal portion. These bands are continued into the lateral ventricle, and expand partly over the posterior horn, and partly over the hippocampus major in the inferior horn. The portion of the fornix which is thus continued into the inferior horn presents a fine concave edge directed inwards, which is the *corpus fimbriatum*.

It would thus appear that the fornix consists of a horizontal triangular portion *(corpus fornicis)* resting on four pillars, which take somewhat of a curved course, and form numerous connections with deep-seated and important portions of the brain. The anterior pillars are closely connected with the optic thalamus, with the tuber cinereum, with the white matter which forms the floor of the ventricle. The posterior pillars are in intimate union with the posterior and middle lobes of the brain.

The fibres of the fornix are distinctly longitudinal. So that, supposing it to be commissural in its office, it may be stated to connect the anterior lobe of the brain and the optic thalamus with the posterior and middle lobes.

The fornix is divisible into two equal and symmetrical portions, one belonging to each cerebral hemisphere. These portions are united, as has been already stated, by the deep-seated transverse fibres of the corpus callosum, and by the terminal fibres of its posterior reflexion, which form, on the inferior surface of the fornix, a peculiar appearance called *the lyra*. The transverse white fibres stand out in relief, crossing at right angles the proper fibres of the fornix. In many subjects, however, this appearance is but faintly indicated.

The horizontal portion of the fornix rests upon a triangular process of pia mater, which is introduced into the interior of the brain, at the fissure beneath the posterior reflexion of the corpus callosum. This process is the *velum interpositum* already described at page 635.

The anterior pillars of the fornix bound in front a space in which the velum interpositum and choroid plexuses unite, and through which the lateral ventricles communicate with each other. This is the *foramen commune anterius*, described by the first Monro.* If a probe be laid transversely in this orifice, it will have above it the anterior extremity of the fornix, in front the anterior pillars, and behind it the point of junction of the three processes of pia mater.

Of the third ventricle.—If the fornix be divided transversely at about its middle, and the segments reflected, and if the velum interpositum be removed, a fissure, *the third ventricle*, is exposed, situate between the optic thalami. This fissure extends forwards between the anterior pillars of the fornix, where it is limited by a band of white matter visible without dissection in that interval. That band is *the anterior commissure*, which lies just in front of, and as a tangent to the convex border of the anterior pillars of the fornix.

At its posterior extremity the third ventricle becomes very much contracted in all its dimensions, and is continuous with a canal which leads to the fourth ventricle *(iter a tertio ad quartum ventriculum, Aqueductus Sylvii)*. The orifice of this canal is apparent at the posterior extremity of the third ventricle, and is bounded superiorly by a transverse cord of white matter, *the posterior commissure*, which extends for a short distance into the cerebral matter on either side. The base of the pineal gland rests upon this commissure.

In this stage of the dissection, a general view of the third ventricle is gained. This cavity evidently results from the apposition of the lateral halves of the brain proper, the parts which more immediately correspond being the inner surfaces of the optic thalami. The depth of the ventricle corresponds, in a great degree, to that of these bodies; but it manifestly increases towards the anterior extremity. Its floor is formed by a layer of grey matter continued from one side to the other, of the same nature as that which has been already described as covering the thalami. The deepest part of the ventricle is an infundibuliform depression, from which the tubular process, seen at the base of the brain *(fig.* 382, *l)*, is continued down to the pituitary body. Just beyond this part is the anterior extremity of the ventricle, situate between the anterior pillars of the fornix and behind the anterior commissure; the depth of which is much less than that of the infundibulum.

The floor of the third ventricle corresponds to several parts of interest which have been enumerated along the middle of the base of the brain. Corresponding to the posterior extremity of the ventricle is the interval between the crura cerebri, the *pons Tarini*, or interpeduncular space. Next in order, in the direction from behind forwards, are the *corpora mamillaria*, which are succeeded by the *tuber cinereum* and *commissure of the optic nerves*. The anterior extremity of the ventricle corresponds to that portion of the tuber cinereum which extends between the optic commissure and the anterior reflection of the corpus callosum.

The roof of the third ventricle is formed by the velum interpositum, already described as giving support to the horizontal portion of the fornix.

* But previously recognised and described by Vieussens.

The direction of the long axis of the third ventricle is obliquely downwards and backwards. Its anterior extremity being on a higher plane than its posterior, is therefore likewise superior.

Pineal gland.—We may here conveniently notice the position and connections of the *pineal gland*. This body, rendered famous by the vague theory of Des Cartes, which viewed it as the chief source of nervous power, is placed just behind the third ventricle, resting in a superficial groove which passes along the median line between the corpora quadrigemina. It is heart-shaped, and of a grey colour. Its apex is directed backwards and downwards, and its base forwards and upwards. A process from the deep layer of the velum interpositum envelopes it and serves to retain it in its place. From each angle of its base there passes off a band of white matter which adheres to the inner surface of each optic thalamus. These processes serve to connect the pineal body to the optic thalami. They are called *the peduncles of the pineal gland*, also *habenæ*. In general they are two in number, one for each optic thalamus. They may be traced forwards as far as the anterior pillars of the fornix. Posteriorly these processes are connected along the median line by some white fibres which adhere to the base of the pineal gland, as well as to the posterior commissure beneath, and which seem to form part of the system of fibres belonging to that commissure. A pair of small bands sometimes pass off from these fibres, along the optic thalami, parallel to the peduncles above described.

It appears, then, that the pineal gland has no other connexion with the brain than that which these *habenæ* or peduncles secure for it; otherwise this body might more appropriately be regarded as an appendage to the pia mater, in which it is involved, and from which it derives its nutrition.

Grains of sand, similar in every respect to those previously described (p. 635) as connected with the internal processes of the pia mater, are found in the pineal body in a large proportion of instances in the adult. They seem to be accumulated as it were in a cavity which is situate towards its base. Hence Soemmering gave to this collection of sabulous matter the name *acervulus*. When, however, the sand is abundant, it may be found upon the surface as well as in the centre.

The anterior commissure.— In examining the third ventricle, a rounded cord of very pure white matter is seen through the interval which is left by the divergence of the anterior pillars of the fornix in their descent to the base of the brain. This band is transverse, and appears to form a tangent to the convex border of those pillars. It may be traced outwards on either side through the anterior extremities of the corpora striata into the white substance of the middle lobes of the brain. A very little dissection is required to expose this cord in its entire extent. It seems placed in a canal hollowed in the cerebral matter. When exposed, its surface is perfectly smooth, indicating that fibres do not pass from it to the wall of the canal in which it lies. Examined in its whole extent, it presents the form of a curve with anterior convexity, and becomes gradually flattened and expanded towards each extremity, its component fibres becoming divergent and mingling with the white substance of that portion of the brain.

This system of fibres possesses the characters of a commissure or bond of connection between symmetrical portions of the brain on either side of the median plane as distinctly as the corpus callosum itself.

The soft commissure.—The cavity of the third ventricle is partly occupied by a lamina of a light grey matter, which extends between the optic thalami of opposite sides. It forms a transverse horizontal plane dividing the ventricle into two portions, one above, the other below it. Sometimes it is divided and disposed as two planes. There is but little power of cohesion between its particles, so that in the recent state the separation of the thalami in the necessary manipulations will frequently cause its rupture. Hence the adjunct "soft" is appropriately applied to it, and by its connecting the thalami of opposite sides, this structure may be ranked with the other commissures. It does not extend throughout the entire length of the ventricle: both its anterior and posterior margins are concave and leave an open space between each extremity of the ventricle.

Thus far our examination includes the topographical anatomy of the cerebrum proper. The pineal body, indeed, scarcely lies within the confines of that segment of the encephalon, but from its internal relation to the third ventricle and the optic thalami, it must be included in the description of those parts. This body rests on the upper surface of that segment of the brain which lies intermediate to the cerebrum, cerebellum, and medulla oblongata, namely, the *mesocephale*. And we shall now proceed to a brief notice of this part and its connection to the other segments.

The mesocephale.—Four eminences are seen immediately behind the third ventricle. A transverse furrow separates them into an anterior and a posterior pair, and a longitudinal furrow along the median line divides the right and left pair from each other. The pineal body rests in the anterior extremity of the longitudinal depression. The anterior pair have been long named the *nates*, the posterior the *testes*. In the human subject the former are the larger. In the inferior mammalia these bodies are much more highly developed than in man, and exhibit a more marked difference of size.

The posterior of the corpora quadrigemina are apparently connected to the cerebellum by two columns of white matter, one of which passes into the central white substance of each cerebellar hemisphere. These are the *processus cerebelli ad testes*. They enter into the formation of the crura cerebelli. Each of them forms the superior layer of the crus cerebelli of its own side.

The interval between the *processus cerebelli ad testes* is occupied by a horizontal stratum of nervous matter composed of a thin layer of grey and of white matter. This is called the *valve of Vieussens,* although there is evidently nothing valvular in its nature or office. Its surface is marked by slight transverse depressions and eminences. The median lobe of the cerebellum overlaps and conceals it from view.

The valve of Vieussens* must be regarded as a portion of the median lobe of the cerebellum, which is extended forwards between the processus cerebelli ad testes. Its constitution is precisely the same as the laminæ of that body, and the transverse markings upon its superior surface are indications of imperfectly developed fissures between the laminæ.

The corpora quadrigemina form the anterior superior part of the mesocephale. They lie above the crura cerebri, upon those columns of nervous matter by which the latter bodies are connected with the medulla oblongata. These columns are continuous above with the optic thalami, and below with the central portion of the medulla oblongata, *the olivary tracts,* or *fasciculi innominati* of Cruveilhier. They are distinguished by their reddish grey colour and their close resemblance in point of structure to the optic thalami. In transverse section they appear as two columns, circular in outline, quite distinct from the surrounding greyish matter in which they seem imbedded (*fig.* 388, *i*).

The lower half of the thickness of the mesocephale is formed by transverse curved fibres with anterior convexity, which extend between the lateral lobes of the cerebellum, and of longitudinal fibres which interlace with the superior layers of those transverse fibres and cross them at right angles. The former constitute the pons Varolii, a great commissure between the hemispheres of the cerebellum; the latter are, in greater part at least, the fibres of the anterior pyramids of the medulla oblongata, which ascend through the pons, and enter into the formation of the inferior layer of each crus cerebri.

In examining the inferior surface of the mesocephale, the pons Varolii, we observe that a longitudinal groove extends along its middle from above downwards. In this lies the basilar artery. Above the anterior edge of the pons, the crura cerebri are seen emerging, and diverging from each other as they pass, to enter, *stalk-like,* into the inferior surface of the cerebral hemispheres. Beneath its posterior edge, the medulla oblongata is seen, its anterior and middle columns passing through the mesocephale to the crura cerebri. On each side the fibres of the pons pass off into each hemisphere of the cerebellum and form the inferior lamina of each crus of that organ.

The cerebellum.—Some account of the general disposition of the cerebellum will serve to conclude this brief review of the topography of the brain. The superior surface of this organ is a little above the level of the quadrigeminal bodies. It is smooth and slightly convex. The lamellæ of the cerebellum are visible upon it, but cannot be separated without removing the arachnoid and pia mater. A notch is seen, dividing the posterior edge into two equal portions, and a larger notch exists in front, at which the cerebellum forms its connection with the mesocephale. These notches denote a subdivision of the organ into two *lateral portions,* or *hemispheres,* and *a median portion.* The superior surface of the median portion is called the *superior vermiform process;* its anterior terminal laminæ form the valve of Vieussens. On the inferior surface the hemispheres of the cerebellum are much more convex than on the superior. The median portion too is somewhat differently arranged on its inferior surface; it consists of a series of laminæ, following a transverse direction; those in its centre are of greater transverse extent than those at either extremity, whence the appearance of a crucial figure results. This is *the inferior vermiform process.*

The posterior margin of the cerebellum is convex, and corresponds to the concave surface of the occipital bone, the falx cerebelli occupying the notch in its middle. Along the line of this margin, the pia mater sinks into a deep fissure, which takes a horizontal direction from behind forwards, and divides the cerebellum into a superior and inferior portion.

As the brain, removed from the cranium, lies with its base upwards, the medulla oblongata is seen between the lateral hemispheres of the cerebellum occupying a portion of the depression between them, in which is the inferior vermiform process (*fig.* 382).

The *fourth ventricle* is a lozenge-shaped cavity situated in the upper and posterior part of the medulla oblongata, and formed by the separation of its postero-lateral columns (*corpora restiformia*). The cerebellum contributes to inclose it above by means of the anterior laminæ of the superior vermiform process and the valve of Vieussens, and below and behind by the inferior vermiform process (*fig.* 386).

We now proceed to the examination of the various segments of the encephalon, with a more special reference to the structure and physiological bearing of each. It may be here remarked that, while all the segments are intimately connected with each other and are therefore mutually dependent, there is much in their structure to justify the assumption that each is capable of exercising an independent function, which is, however, liable to be modified by the influence which any one, or all of the other segments may have upon it.

Of the medulla oblongata. (Fr. *moelle*

* *Valvula cerebri major* is the name which Vieussens applied to this process. He describes it as "membrana quam transversus medullaris tractus circa anteriora subit, processui vermiformi anteriori, processibus a cerebello ad testes et posticæ pontis Varolii parti adhæret et unitur." He further adds, "illam valvulæ vices gerere asserimus. Ex quo fit, ut habitâ officii et magnitudinis illius ratione, ipsam valvulam cerebri majorem nominemus, ut eam a membranaceis ligamentis distinguamus, quæ intra longitudinalis et lateralium sinuum cavitates valvularum minorum vices supplent et munia præstant."—*Neurographia Universalis,* p. 76. Ed. Lugd. 1716.

allongée, bulbe rachidien. Germ. *das Verlangerte Mark.* Ital. *midollo allungato.)*—We begin with the description of this segment because of its immediate connection with the spinal cord, for it is plain, since this is the connecting link between that centre and the intra-cranial mass, that whatever influence the latter may exercise upon the former, must be conveyed or propagated by the medulla oblongata.

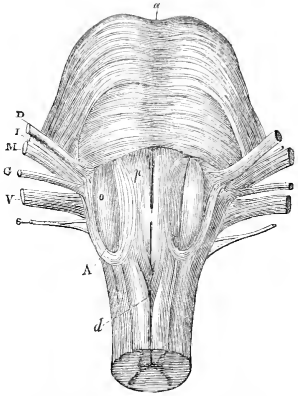
It is proper to notice that the term *medulla oblongata* has not been employed in a uniform sense by all anatomists. Willis and Vieussens comprehended under this title all the parts from the corpora striata and optic thalami (both included) down to the commencement of the spinal cord.* The same signification was adopted by the writers who immediately followed these great anatomists. Winslow considers the medulla oblongata as "one middle medullary basis common to both cerebrum and cerebellum, by the reciprocal continuity of their medullary substances."† The *crura,* or *pedunculi cerebri,* constitute its anterior part: these seem to be lost in the corpora striata, as Winslow states, and therefore they are looked upon as the peduncles of the cerebrum. Its posterior portion is called the *extremity* or *cauda* of the medulla oblongata *(queue de la moelle allongée).* It is to this latter portion that Haller restricted the term medulla oblongata, and most modern anatomists follow his example. Rolando, however, still applies the term in its more extended sense.

In the present article, we adopt the phraseology of Haller as far as regards the term *medulla oblongata.* It seems to form an upper enlarged portion of the medulla spinalis, to which it stands in somewhat the same relation as the capital to the shaft of a column. Its superior limit is indicated by the posterior edge of the pons Varolii; its inferior is denoted by a horizontal plane extended between the occipital foramen and the first vertebra. A more natural line of demarcation, however, between this part and the medulla spinalis may be found in certain decussating fibres which are seen crossing the anterior median fissure of the former at its inferior extremity. No such limit as this, however, is found on the posterior surface *(fig.* 383).

The medulla oblongata has somewhat of a conical shape, its base being situate above at the posterior margin of the pons. It is slightly flattened on both anterior and posterior surfaces, more so on the latter than on the former.

The medulla oblongata admits of the same primary subdivision as the medulla spinalis, namely, into two equal and symmetrical portions separated from each other by an anterior and a posterior median fissure. The former is wide but not of great depth. It is occupied by a fold of pia mater. Its floor is formed by a layer of fibrous matter which has the same cribriform appearance as that of the anterior spinal fissure. These fibres are commissural, connecting the two portions of the medulla oblongata. The posterior fissure is very deep and narrow. It is not limited in front by a grey commissure as the posterior spinal fissure is, but by the posterior surface of the white commissure just described. A single layer of the pia mater passes into it. The continuity of the anterior fissure of the medulla oblongata and of that of the spinal cord is interrupted by the decussating fibres of the pyramids, *(fig.* 383, *d,)* but the posterior fissures are distinctly continuous with each other.

Fig. 383.



Anterior view of the medulla oblongata and pons Varolii. (After Arnold.)

a, anterior extremity of the pons.
p, anterior pyramids.
d, decussating fibres of anterior pyramids.
o, olivary bodies.
A, arciform fibres.
D, portio dura; I, portio intermedia of Wrisberg; M, portio mollis — Seventh pair of nerves.
G, glosso-pharyngeal nerve; V, par vagum; S, spinal accessory — Eighth pair of nerves.

On either side of the median plane there are indications on the surface of the medulla oblongata, which suggest a subdivision of each half of the organ into four columns of nervous matter, through the medium of which it forms its connection with certain parts of the cerebrum and cerebellum on the one hand, and of the spinal cord on the other. These columns are the *anterior pyramidal,* the *olivary,* the *restiform,* and the *posterior pyramidal.*

The anterior pyramidal columns, or *anterior pyramids, (figs.* 383, 384, 385, *p,)* are two prismatic bundles of fibrous matter which extend between the antero-lateral columns of the spinal cord and the lateral hemispheres of the brain. In the medulla oblongata each of these columns forms a compact body, which, when cut transversely, exhibits a triangular outline in its central portion, but that of a cylinder at either extremity. Each pyramid is limited on the outside by a superficial groove, which separates it from the olivary column, and on the inside by the anterior median fis-

sure. Superiorly the pyramids pass into the mesocephale above the inferior fibres of the pons Varolii, and interlace with other fibres of the same system which occupy a more elevated plane. In its passage into the mesocephale, each pyramid experiences a marked constriction, which alters its form from a prism to a cylinder. The fibres, however, soon diverge and expand. As they ascend through the mesocephale they are crossed by the transverse fibres of the pons, and some grey matter occupies the interstices between them, with which it is probable that other fibres are connected, and are added to those of the pyramids, as they emerge from the mesocephale at its anterior extremity.

The pyramids gradually diminish in size towards the inferior extremity of the medulla oblongata. And here three sets of fibres may be distinctly noticed. The first, or *decussating fibres*, are the most numerous; they pass downwards and backwards into the antero-lateral column of the spinal cord on the opposite side, so that the right pyramid sends fibres into the left half of the cord, and the left pyramid into the right half of the cord. These decussating fibres consist of from three to five bundles from each pyramid, which in their descent cross and interlace with each other (*figs.* 384, 385, *d*). They differ in distinctness as well as in number in various subjects. The point at which the decussation takes place is about ten lines below the margin of the pons Varolii, and the interruption to the fissure, occasioned by the crossing of the fibres, occupies a space of from two to four lines. To expose these fibres clearly it is necessary to remove the pia mater carefully from the anterior surface of the medulla oblongata to some distance below the decussation, and it is, in general, of advantage to the preparation to place it in alcohol immediately after the removal of the pia mater.

A second set of fibres, very few in number, are continued from the pyramids directly down to the anterior surface of the cord on the same side, and appear to be continuous with some of the superficial fibres of the antero-lateral column. These fibres may be regarded as the direct channel of communication of each half of the medulla oblongata with the corresponding half of the spinal cord (*fig.* 385, *n*).

The third series of fibres vary considerably in point of developement in different individuals. They pass between the pyramids and the postero-lateral columns of the medulla oblongata, the restiform columns. They form a series of curves with their concavities directed upwards (*fig.* 383, A), crossing beneath the inferior extremity of the olivary body, and sometimes extending over a considerable portion of its surface. I have on several occasions seen these fibres so largely developed as to cover nearly the whole surface of each olivary body. These fibres are appropriately distinguished by the name *arciform* from their arched course (*processus arciformes*, Santorini).

When these fibres are so numerous as to cover the surface of the olivary body, we may observe that those which are nearest the margin

of the pons Varolii are the least curved, and in some rare instances the uppermost ones exhibit no more curvature than the posterior fibres of the pons.

Both Santorini and Rolando have figured these fibres in their most highly developed state. The delineation given by the latter author, whilst it serves admirably as a diagram to show the general relation of the fibres, represents them as more numerous and distinct than I have ever had an opportunity of seeing them, and likewise exhibits them as passing upwards through the pons. This is certainly not the case. These fibres appear to incorporate themselves with the restiform bodies which connect the medulla oblongata with the cerebellum.

It seems to me that the arciform fibres may be properly regarded as a part of the same system as those which form the pons Varolii. They are largely developed in some quadrupeds, although they assume a different form. The fibres which constitute what Treviranus called *the trapezium*, appear to answer the same purpose as the arciform fibres; but, by reason of the non-developement of the olivary bodies on the exterior of the medulla oblongata, they do not take the curved course, which characterizes them in the human subject. These fibres cross the anterior surface of the medulla oblongata parallel to but distinct from the pons Varolii. They connect the pyramids and restiform bodies on each side.

By their continuation upwards the pyramidal bodies form a connection with the mesocephale, and also with the hemispheres of the brain through the medium principally of the corpora striata, and perhaps also of the optic thalami. Through the decussation of fibres which takes place just before the pyramids sink into the spinal cord, each cerebral hemisphere is connected with that half of the spinal cord which belongs to the opposite side of the body. By this arrangement is explained the influence which cerebral disease exercises upon the side of the body opposite to that on which it occurs. If the right hemisphere be irritated, convulsions are produced on the left side; if the right hemisphere be compressed, the left arm and leg and side of the face will be paralysed. So constant is this "crossed" influence of cerebral lesion that it can be attributed only to some uniform physical condition of the nervous centres. And that the anatomical disposition on which it depends is situate at the lower part of the medulla oblongata is proved, not only by the existence of these decussating fibres at this situation, but likewise by facts revealed by the phenomena of disease, and the results of experiment. Morbid lesions, for example, which have their seat *above* the decussation are, with rare exceptions, accompanied by affection of the opposite half of the body—those which involve the nervous centre *below* the decussation affect the body on the same side. Mechanical injury to the brain or spinal cord produces like effects. And so constantly is this the case that when we meet a case of paralysis or of convulsion affecting only one side, we confidently predict that the lesion on which it depends will be found on the opposite side of the brain.

This law of cerebral action has been known from the earliest periods of medical science, but the anatomical explanation of it, the suggestion of which dates as far back as the time of Aretæus,* has been generally admitted only within a comparatively recent period. This explanation was founded on the hypothesis of a decussation of fibres in the medulla oblongata to a greater or less extent. Santorini, indeed, laid it down that decussation took place not only in the lower part of the medulla oblongata, but likewise at the anterior and posterior margins of the pons Varolii.† But it is quite impossible, by our ordinary means of observation, to detect any such connection between the anterior pyramids elsewhere than at their inferior extremity. In many instances I have thought that the fibres of the commissure which forms the floor of the anterior fissure presented an appearance as if decussation took place along the entire length of the pyramids. But the numerous foramina by which the commissure is penetrated to give passage to vessels for the central substance of the medulla, are very apt to give rise to a fallacious appearance of this kind.

It has been stated that there are exceptions to this law of cerebral action. Such certainly must be extremely rare, for in the course of a considerable experience for many years I have not met with an unequivocal instance in which paralysis occurred on the same side with cerebral lesion. The analysis which Burdach has given of 268 cases of paralysis in which there was lesion of a single hemisphere, shows very strikingly how rare must such an exception be. Of these cases he states that 10 were accompanied with paralysis of both sides, and that 258 had hemiplegia. And of the hemiplegic cases, the paralysis occurred on the same side as the cerebral lesion in only 15.

The full explanation of these exceptions has

* Περι αιτιων και σημειων χρονιων παθων, βιβλ. Α, κεφ. ζ, p. 87, Ed. Kuhn.

† Santorini must have been well acquainted with the decussating fibres of the pyramids, which he clearly describes. The whole passage is worth being quoted here. "Id autem triplici potissimum in loco animadvertere potuimus; in utraque scilicet priore, posterioreque annularis protuberantiæ crepidine atque maxime in imo medullaris caudicis quâ in spinalem abit. In priore itaque annularis protuberantiæ parte, quâ superius reflexa pro comprehendendis oblongatæ medullæ cruribus in anguli formam interiùs producta tenuatur, sic ex concurrentibus fibris, strictiorique agmine coeuntibus altera alteram scandit ut præter mirum implexum decussatio luculentissimé appareat. Idipsum fermé in postica ipsius crepidine occurrit. Eo iterum in loco, qui quarto ventriculo subjicitur, præter varios fibrarum ordines et colores, in adversum latus productas et decussatas fibras commodé spectavimus. Si ea tamen evidenter uspiam conspicitur, profectò quam evidentissimè duas vix lineas infra pyramidalia atque adeo olivaria corpora conspici potest. Quà enim in longitudinem producta linea seu rimula pyramidalia corpora discernuntur, si leniter deducantur, probè prius eo potissimum loco arctissimè hærente tenui meninge nudata, non tenues decussari fibrillas, sed validos earundem fasciculos in adversa contendere, quam apertissimè demonstrabunt." Obcrv. Anat. cap. iii. § xii. p. 61. Ed. Lugd. Bat. 1739.

yet to be discovered. The anatomical connection of each anterior pyramid with the spinal cord, however, affords some clue to it. This takes place, it will be remembered, not by the decussating fibres only, but by straight and perpendicular ones also; so that each pyramid is connected with both halves of the spinal cord, first and principally with the opposite half; and, secondly, and by much fewer fibres, with that of the same side. When those parts of the brain are affected, with which the decussating fibres are connected, the paralysis will be crossed; when, on the other hand, the direct fibres are engaged, the paralytic affection will occur on the same side of the body as that on which the lesion has occurred. But even on this explanation it is difficult to understand how these latter cases should be of such rare occurrence, and still more, how hemiplegia is so frequently accompanied with a perfect state of sensation and motion on the other side. In the present state of our knowledge, however, this is the only contribution which anatomy can offer towards the determination of this difficult question.

Of the restiform bodies.—The lateral, and, in great part, the posterior portion of the medulla oblongata is formed on each side by a thick and rounded *rope-like* column, called the *corpus restiforme*. It is composed chiefly of fibrous matter, and its constituent fibres take a longitudinal direction. There is no line of demarcation between them and the fibres of the spinal cord, with the antero-lateral and posterior columns of which they seem to be continuous. Traced upwards, the restiform bodies pass a little outwards, and by their divergence contribute to the increased size of the medulla oblongata at its base.

To see the connexions of these bodies completely, the posterior surface of the medulla oblongata should be examined. The restiform bodies form the greater part of this surface. They increase in thickness as they ascend. Their outer margin forms a gentle curve, which is concave. Their inner border is connected in its lower portion to two small bands of fibrous matter, between which the posterior median fissure is situate; these are the *posterior pyramids* (Y, *fig.* 386). In its upper portion, the inner border of each restiform body is free, and forms the outer boundary of a lozenge-shaped depression, *the fourth ventricle.* Whilst the connection of the cerebellum with the posterior surface of the medulla oblongata is undisturbed, the exact relation of these bodies to the ventricle cannot be seen. It is necessary to raise up the inferior portion of the median lobe of the cerebellum, to expose the cavity of the ventricle; or this may be effected by dividing the median lobe along the middle line.

Fig. 386.

R, corpus dentatum or rhomboideum.

Each restiform body ascends to the hemisphere of the cerebellum of the corresponding side. The whole of its fibres appear to penetrate that organ, and contribute to the formation of its crus, the middle layer or peduncle of which it forms. This is very well shown in the analytical figure at p. 667, (*fig.* 380,) where *r* is the restiform body passing upwards and outwards into the hemisphere of the cerebellum.

The distinction between the restiform and olivary bodies on the surface is indicated by the line of origin of the eighth pair of nerves, which may be said to emerge along the anterior margin of the former. A narrow band of fibres, very distinct in some brains, occupies the depression between the posterior edge of the prominent olivary body and the line of emergence of these nerves. This band has been well delineated by Rolando, Reid, and others; it probably forms a part of the cerebral fibres of the medulla oblongata, and ascends through the pons.

The direction of the fibres of the restiform bodies is longitudinal. Those which are situate most posteriorly pass directly downwards, and are distinctly continuous with the posterior columns of the spinal cord. The fibres which form the lateral and anterior part of the restiform bodies pass downwards and forwards to the antero-lateral columns. A superficial groove, varying very much in distinctness in different subjects, which passes upwards from the line of emergence of the posterior roots of the spinal nerves, indicates the distinction of these two sets of fibres. If the posterior column be separated from the antero-lateral in the spinal cord, the separation may be easily carried upwards along this line, in a specimen which has been sufficiently hardened.

From the description now given, the restiform bodies may be regarded as the connecting fibres between the cerebellum and the spinal cord. They may be designated the *cerebellar fibres* of the medulla oblongata in contradistinction to the others, which are entirely connected with the mesocephale and with the cerebrum.

Rolando describes the restiform body as containing grey matter—the *grey tubercle* of Rolando. This grey matter, however, may be more correctly regarded as a portion of the central nucleus of the medulla, from which very probably some fibres of the restiform body emerge.

The posterior pyramidal columns.—On each side of the posterior fissure we find a narrow column, sufficiently distinct from the restiform columns. These may be traced downwards through the cervical region of the cord, and even into the dorsal or lumbar, according to Foville. They taper gradually to a fine point, the situation of which varies in different subjects. Superiorly they form the inferior and part of the lateral boundary of the fourth ventricle. Their innermost fibres end abruptly in a blunt extremity, whilst the external ones are continued upwards on each side of the ventricle (*fig.* 386, Y).

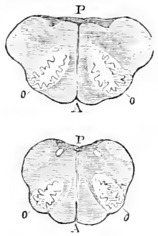
Olivary columns.—The oval bodies, which form a relief upon the surface of the medulla oblongata, have been long known by the names *corpora olivaria, olivæ.* They occupy the interval between the anterior pyramids and the restiform bodies, separated, however, from the latter by the narrow band of fibrous matter above described.

The surface of each olivary body is crossed to a greater or less extent by the arciform fibres, as already described. Sometimes it is necessary to remove these fibres, in order to expose the proper texture of the olives.

The superficial layer of each olivary body is evidently fibrous, and the constituent fibres seem to take a longitudinal course. If a section be made so as to remove the prominent convexity of this body, it will be seen that the white matter of which it principally consists encloses a layer of vesicular or grey matter disposed in a peculiar manner. This grey layer presents the appearance of a waving line enclosing white matter. If the section of the olivary body be made transversely, the grey waving line is still present, but it presents a convex border outwards, and is open within, being evidently continuous with the central and less definitely disposed grey matter of the medulla. And when the section is vertical, and so as to divide the olivary body in its entire length, the convex border of the grey line is still external, but it is open towards the interior of the medulla.

This grey layer, contained within the olivary

Fig. 387.



Transverse sections of the medulla oblongata.

o, olivary bodies, in which are seen the undulating line of grey matter which forms the corpus dentatum.

body, is called the *corpus dentatum* (*corps festonné*, Fr.) It is evidently a capsule of vesicular matter continuous below with that of the cord, internally with that of the central substance of the medulla oblongata, and superiorly with that of the mesocephale (*o, fig.* 387). Its disposition, in a convoluted form, has doubtless reference to the packing of a certain quantity of this matter into a given space, and to the important object of bringing the vesicular and fibrous matter into connection as extensively as possible.

It has been very commonly supposed that the olivary bodies are mere gangliform masses laid upon certain ascending fibres of the medulla, and that they may be readily removed without injury to the deeper-seated parts. Either of the two following modes of dissection will, however, serve to point out the erroneousness of this view. If the anterior pyramids be removed, a concave surface is left between the two olivary bodies, in which their continuity with the central substance of the medulla is distinctly seen. This central substance, which forms a substratum on which the anterior pyramids rest, and from which it is not improbable that some of the fibres of the pyramids emerge, is of considerable density. Each olivary body appears gradually to merge into it; or, adopting another mode of description, it seems to protrude, forming a relief on the exterior, in the interval between the pyramidal and restiform bodies on each side. Or a transverse section, as in *fig.* 387, will exhibit a similar continuity between the olivary bodies and the central substance of the medulla.

According to this view, then, the existence of the olivary bodies in the human brain and that of the Quadrumana indicates a high developement of the central substance of the medulla oblongata as compared with its other nervous columns. In all the vertebrate animals below man, the medulla oblongata increases with the bulk of the body, and like the spinal cord evidently bears a direct relation to it. This high developement appears, however, to affect more especially the restiform and pyramidal bodies, and their connecting fibres, *the trapezium*. The former do not leave any space between them, and the central columns do not extend to the surface; and from the absence of any great developement of grey matter, we find no such arrangement as that which gives rise to the *corpus dentatum* in man.

The olivary or central columns of the medulla oblongata pass into the mesocephale, occupying a plane superior to that of the pyramidal fibres and of the transverse fibres. They may be traced upwards to the crus cerebri, where they seem to merge into the optic thalami, and to form a connection with the corpora quadrigemina posteriorly.

These columns are seen distinctly in their ascent to the brain in the fourth ventricle, as two cylindrical columns (A, F, *fig.* 386). They form the floor of that cavity and are separated from each other by the longitudinal fissure which is continued upwards from the posterior fissure of the medulla oblongata.

In the fourth ventricle the olivary columns are crossed by the fibres of origin of the portio mollis of the seventh pair of nerves, the white colour of which in the recent specimen contrasts strikingly with the greyish hue of the columns themselves. We here see distinctly that these columns are the source of origin of these nerves, and no doubt they are equally so of all the nerves which are connected with the medulla oblongata, namely, the fifth pair, the eighth, the ninth, and probably also of the sixth.

The relation of the olivary columns in their upward course, to the other constituents of the mesocephale and crura cerebri, may be conveniently demonstrated in examining tranverse sections of those parts. We shall, therefore, return to this subject in describing the anatomy of those portions of the brain.

The following interpretation of the various columns of the medulla oblongata, referred to in the preceding description, has much foundation in their anatomical relations.

The olivary or central columns constitute the fundamental part of the medulla oblongata; that, on which its action as a distinct and independent centre depends, and in which the proper nerves of this segment of the encephalon are implanted. The continuity of those columns with the optic thalami and corpora quadrigemina materially enhances their physiological influence, and denotes their intimate association with some of the most important functions of the brain. And it may be added, that this connection of the medulla oblongata with parts which are ordinarily described as pertaining to the brain itself, shews that the original application of the term by Willis and Vieussens to a much greater extent of the encephalon is certainly more consistent with the physiological anatomy than that which is now employed for the convenience of description. There can be no doubt that the extent of this central and fundamental portion of the nervous system is limited above by the optic thalami and below by the spinal cord.

The anterior pyramids connect the cerebral hemispheres with the spinal cord, the principal bundles of fibres decussating each other on the middle line, so that the right pyramid is the medium of connection by the greater number of its fibres between the right hemisphere of the brain and the left half of the cord, but by a much smaller number between that same hemisphere and the right half of the cord. And so also of the left, *mutatis mutandis*. It is highly probable too that the anterior pyramids derive fibres from the locus niger of the crus cerebri and the vesicular matter of the mesocephale. These fibres, therefore, connect those segments with the spinal cord, but whether they contribute to the formation of the decussating or non-decussating bundles, or to that of both, it is impossible to determine.

The restiform bodies are evidently the connecting fibres between the hemispheres of the cerebellum and the posterior and antero-lateral columns of the spinal cord. And the posterior pyramids connect the posterior part of the medulla oblongata with the cervical and dorsal regions of the cord.

Nerves.—Numerous nerves are connected with the medulla oblongata—a fact which serves greatly to enhance its importance as a centre of nervous action. These nerves are the sixth pair, which are connected with the anterior pyramids just behind the posterior border of the pons; the ninth pair, or hypoglossal nerves, which emerge along the anterior border of the olivary body; the seventh pair (*portio mollis* and *portio dura*), which emerge just behind the upper extremity of the olivary body; and the eighth pair, which arise along the posterior margin of the olivary body.

OF THE MESOCEPHALE. — The pyramidal and olivary columns may be readily traced, as already explained, from the medulla oblongata up to the cerebral hemispheres; the former becoming united chiefly with the corpora striata, the latter with the optic thalami.

In that part of their course which is intermediate to the medulla oblongata these columns become mingled with certain transverse fibres, and with more or less of vesicular matter, and with them contribute to form a mass which is the connecting link between all the segments of the cerebellum, and may be compared to a railroad station, at which several lines meet and cross each other. This is the *mesocephale* or *mesencephale*. The name was suggested by Chaussier, inasmuch as it forms "to a certain extent the middle and central part of the encephalic organ, the bond which unites the several bundles of fibres which contribute to its formation."

The mesocephale may be isolated from the other segments by dividing the crura cerebri just beyond the anterior margin of the pons, and the crura cerebelli as they penetrate the hemispheres, and the medulla oblongata on a level with the posterior edge of the pons. The crura cerebri emerge from it in front: the medulla oblongata is connected with its posterior surface: on either side it is prolonged into a crus cerebelli. Its inferior surface, which is very convex and looks forwards, is composed of the thick layer of arched fibres which form the *pons Varolii;* and on its superior surface, which looks backwards, are the corpora quadrigemina, the processus cerebelli ad testes, and part of the floor of the fourth ventricle (*fig.* 386).

According to Chaussier, its weight is equal to about the sixtieth or sixty-fifth part of the entire brain.

We shall describe separately the inferior and the superior surfaces of this segment of the encephalon, and its intimate structure as unfolded by sections.

The inferior surface, (*pons Varolii, annular protuberance,*) convex from side to side, is interrupted along the median plane from behind forwards by a shallow groove in which the basilar artery usually lies, giving off in its course numerous minute capillaries to the nervous structure of the mesocephale.

When the pia mater has been stripped off this surface, it is seen to be very evidently composed of a series of transverse fibres which take an arched course. The fibres are collected into large fascicles separated from each other by very distinct intervals, so that there is no part where the fibrous structure is more apparent than here. They form arcs of circles, not concentric, lying one behind the other in a series nearly parallel. Owing to this want of complete parallelism the width of this surface measured from before backwards is much less at each extremity than in the centre. The anterior margin is convex, and forms a thick edge crossing the crura cerebri like a bridge; hence the term *pons* was applied by Varolius to the whole series of fibres. The posterior border is concave, less curved than the anterior, and crosses the anterior pyramids and olivary columns, as the latter does the crura cerebri. The intervening fascicles of fibres become gradually less curved as they approach the posterior margin.

These transverse fibres form a stratum of considerable thickness at the inferior surface of the mesocephale. Some grey matter is deposited between the less superficial layers which constitute it. The more deep-seated layers are penetrated and crossed at right angles by the ascending fibres of the anterior pyramids. A remarkable interlacement takes place at this situation between the vertical and transverse fibres—the latter passing alternately in front of and behind adjacent bundles of the former. Some of the vertical fibres seem to sink into and connect themselves with the grey matter.

A transverse vertical section of the mesocephale gives a more complete view of the exact extent of the transverse fibres. They are found to occupy rather more than one-third of the depth of the exposed surface. Their disposition in laminæ is very apparent. Those which are nearest the centre of the mesocephale have between them considerable intervals, which are filled up by grey matter, through which pass vertically the fibres of the pyramids. The intervals between the laminæ gradually diminish towards the inferior surface of the pons, and the quantity of intervening grey matter becomes proportionally less, and disappears altogether from between those laminæ the intervals of which are not traversed by the fibres of the pyramids.

The transverse fibres pass on either side into each hemisphere of the cerebellum, contributing with the *processus cerebelli ad testes* and the restiform bodies to form the *crura cerebelli.* They are the *inferior peduncles* of these crura.

The anatomy of these transverse fibres evidently denotes that they serve to connect the right and left cerebellar hemispheres, as *commissures,* and in a manner strikingly analogous to that in which the fibres of the corpus callosum connect the cerebral hemispheres. This view of the office of these fibres is strongly confirmed by the fact that their number is always in the direct ratio of the size of the lateral hemispheres, and that when the hemispheres are absent, these fibres no longer exist. When, therefore, the cerebellum consists only of a median lobe, there is no pons Varolii.

Some of the transverse fibres nearer the inferior surface appear to dip in along the median line, and to pass upwards and backwards, forming a vertical plane of fibres which divides the mesocephale into two symmetrical portions, and Chaussier imagined that a decussation took place at this situation. The groove in which the basilar artery lies is formed partly by the greater condensation which is produced along the median plane by this arrangement, and partly by the slight bulging on either side of it, caused by the ascent of the anterior pyramids. These fibres are continuous with a series of similar ones in the medulla oblongata (*antero-posterior fibres* of Cruveilhier).

The extent of the superior surface of the mesocephale may be limited in front by a line which passes from side to side just before the anterior of the corpora quadrigemina, and posteriorly by the base of the valve of Vieussens. This occupies a much greater space than the inferior surface. It is an inclined plane, and passes downwards and backwards, being concealed by the anterior laminæ of the superior vermiform process of the cerebellum and the posterior border of the corpus callosum.

The *corpora* or *tubercula quadrigemina* are four rounded eminences—gangliform bodies—disposed in pairs (*fig.* 386, D, D'). The anterior pair are larger than the posterior. The former have been distinguished as the *nates,* the latter the *testes.** These bodies are situate further forwards than the pons, and are chiefly connected with the superior surface of each crus cerebri.

The nates are of a deeper grey colour than the testes. In this respect they resemble the optic thalami. Both pairs are similar in structure to those bodies. When cut into, they appear to consist of fibrous matter intermingled with vesicular. Thin sections examined with the microscope exhibit intricate interlacements of tubular fibres with vesicular matter interposed—a true ganglionic structure.

An important fact deserves special notice as indicating that vesicular matter is found in

* In reference to these absurd appellations Willis has the following remark: "Prominentia orbicularis —quarum usus longè nobilior videtur, quam ut viliora ista natium et testium nomina mereantur."

these bodies in considerable quantity. The pia mater which adheres to their surface abounds in minute bloodvessels, and in separating it these are seen to penetrate the tubercles in vast numbers. This layer of pia mater contributes to form the velum interpositum.

The quadrigeminal bodies are the analogues of the optic lobes in birds, reptiles, and fishes. In these classes there is only a single pair of tubercles. They are of considerable size in birds, and form a conspicuous portion of their encephalon. The division into four takes place only in Mammalia. The anterior are the larger in herbivorous animals, the posterior in the Carnivora. In most quadrupeds these bodies are concealed from view by the posterior lobes of the brain; but in Rodentia they are exposed in consequence of the imperfect developement of the brain in the backward direction.

The quadrigeminal bodies rest upon two processes of fibrous matter, which extend backwards to the median lobe of the cerebellum, and forwards to the optic thalami. These processes form a connection between the thalami and the quadrigeminal bodies and the cerebellum. They have been variously designated *processus cerebelli ad testes, processus cerebelli ad corpora quadrigemina, processus cerebelli ad cerebrum.*

The *valve of Vieussens* intervenes between these processes, and closes the fourth ventricle at its upper part.

A longitudinal groove separates the right and left pair of quadrigeminal bodies. The anterior extremity of this groove forms an expanded and somewhat flattened surface on which rests the pineal gland (*fig.* 386, S). From the posterior extremity a small band extends to the valve of Vieussens, called *frenum*. An incision made vertically downwards along the course of this groove exposes the canal through which the fourth ventricle and the third communicate (*iter a tertio ad quartum ventriculum*). This canal communicates with the posterior part of the third ventricle by an opening which is situate beneath the posterior commissure, and with the superior extremity of the fourth ventricle beneath the valve of Vieussens.

The fourth pair of nerves are seen upon this surface, attaching themselves to the processus cerebelli ad testes, or to the Vieussenian valve, or to the posterior pair of quadrigeminal bodies.

Besides the anterior pyramids, the olivary columns are continued through the mesocephale to form with the former the crura cerebri. These columns are exposed along the floor of the fourth ventricle; higher up, however, they are surrounded by a lightish grey matter, form the superior stratum of each crus cerebri, separated from the quadrigeminal tubercles by the processus cerebelli, and finally merge into the optic thalami. Their course is well displayed in *fig.* 380, where *f* represents the olivary columns, *t* the processus cerebelli ad testes, and *v* the pons penetrated by *p*, the pyramids.

The olivary columns retain their greyish hue in their upward course. Their cylindrical form is very apparent on the floor of the fourth ventricle; but it is still more obvious on viewing a transverse section, when each olivary column appears as a cylinder, to be distinguished from the rest by its roundness and its peculiar colour.

No other mode of dissection conveys so much knowledge of the anatomy of this part as a transverse section, carried from above downwards through either pair of quadrigeminal bodies, and inclined a little backwards, so as to pass through the pons. The parts which may be observed on such a section, enumerated from above downwards,—are, 1, either pair of quadrigeminal tubercles; 2, between and beneath them, the iter cut across; 3, on either side of this, fibrous matter; 4, below this on each side, the section of each olivary column; 5, planes of transverse fibres interlacing with longitudinal ones, and grey matter between the planes; 6, transverse fibres forming the pons Varolii.

Fig. 333.

i i, olivary columns.
n, locus niger.
a, the inferior plane of fibres diverging upwards, which are continuous with the anterior pyramids.

From the preceding description of the mesocephale it may be concluded that two classes of elements enter into its formation. These are *intrinsic* and *extrinsic*. The former consists in the masses of vesicular matter, with which the fibrous matter, whatever be its course, is intimately connected. Such are the grey matter of the quadrigeminal bodies; that light grey matter which surrounds the olivary columns in their upward course; the darker matter which intervenes between the transverse fibrous lamellæ; and more in front, that which forms the locus niger of the crus cerebri.

The *extrinsic* elements are those which pass through this segment, being continuous with some portion of a neighbouring segment, or serving to connect the grey matter of the mesocephale with the hemispheres of the cerebrum or cerebellum, or with the medulla oblongata. The fibres which form the inferior layer of the pons are perhaps the only element that does not connect itself in some way with the grey matter of the mesocephale, since they seem simply to pass across from one crus cerebelli to the other. The deeper transverse fibres, the pyramids, the olivary columns, the processus cerebelli ad testes, all connect neighbouring parts with the intrinsic matter of the mesocephale.

It is plain, then, that anatomy affords abundant grounds for the conclusion, that the mesocephale must be regarded as a distinct centre, connected by numerous bonds of union with the other segments of the brain.

If further proof of this were wanting, it would be found in the connexion of two important nerves with this segment. These are the fifth and the fourth pair. The former penetrate between the superficial fibres of the pons which spread out upon the crus cerebelli; the latter are connected with the superior surface of the mesocephale.

OF THE CEREBELLUM.—(παρεγκεφαλις, οπισθιος εγκεφαλις; Fr. *cervelet;* Germ. *Kleine Gehirn.*) This remarkable portion of the encephalon, so called from its general resemblance to the cerebrum, of which it is, as it were, the diminutive, is situate behind the mesocephale and medulla oblongata. It is lodged in a compartment of the cranium, the floor of which is formed by the fossæ of the occipital bone, and which is separated from the cavity occupied by the cerebrum, by the horizontal process of the dura mater, previously described as the *tentorium cerebelli.* This process forms a partition between the inferior surface of the posterior lobes and the superior surface of the cerebellum.

The cerebellum, like the cerebrum, is at its highest point of developement in the human subject. It exists as a very distinct portion of the encephalon in all the classes of vertebrate animals, and exhibits a marked gradation of increase from Fishes, through Reptiles and Birds, up to Mammals.

In Fishes and Reptiles it consists of a single lobe, overhanging the posterior surface of the medulla oblongata, and closing the fourth ventricle partially like a valve. It is, in general in these classes, smooth on its surface, and exhibits no complication of structure, no subdivision into laminæ. But in the sharks a manifest increase in size and an incipient lamellar arrangement are distinctly observable, which shew that in them this organ is more highly developed than in any other fishes.

In birds a similar complication of structure takes place to a much greater extent, and a lateral lobe or appendage is added on each side to the single central organ which constitutes the cerebellum of fishes and reptiles. And in the mammiferous series, the lateral lobes along with the central portion experience a progressive augmentation of size (proportionally to the body), and a corresponding complexity of structure up to the quadrumana and man.

The best and most obvious subdivision of the human cerebellum is into the *median lobe* and the *lateral lobes* or *hemispheres.* The former is the fundamental and primitive portion of the organ; the latter, although each exceeds the median lobe in size, and therefore they conjointly form far the largest portion of the cerebellum, are appendages, which in man assume great physiological importance. The median lobe has likewise been called *vermiform process,* the upper and lower laminæ being distinguished as the *superior* and *inferior vermiform processes.*

From the tables already given it would appear that the cerebrum is to the cerebellum in the proportion of 8 or 9 to 1 in the adult, and in the infant, according to Chaussier, as 16 or 18 to 1. The average weight of the cerebellum is, according to Professor Reid's researches, 5 oz. 4 dr. in the male, and 4 oz. 12 dr. in the female.

The cerebellum seems to keep pace, in its developement, with that of the cerebrum. It attains its greatest size, both in male and female, at the same age as the cerebrum. At the most advanced ages, however, it seems to diminish with greater rapidity than that organ.

Some variety appears to occur as regards the relative developement of cerebellum to cerebrum in the adult. Chaussier remarks that he had in some instances found the cerebellum equal to a seventh or a sixth part of the weight of the cerebrum, but rarely the eleventh or twelfth.

There do not appear to be any good grounds for the assertion that the cerebellum is more developed in proportion to the brain in the female than in the male. Professor Reid's extensive series of researches show, beyond all question, that it maintains the same proportionate bulk in both sexes.

It has also been asserted that castration, or disease of the genital organs, such as would destroy the generative instinct, causes wasting of the cerebellum. If both testicles be removed, the whole cerebellum, it is said, degenerates; if only one, the hemisphere of the opposite side is affected.

The most complete refutation of this assertion is afforded by M. Leuret's series of observations of the brains of geldings and entire horses. These researches, indeed, shew that in stallions the cerebellum is proportionally smaller than in mares or geldings, and that in geldings it is larger than in mares. It is very evident from them that mutilation of the sexual organs does not cause degeneration of the cerebellum.

The shape of the cerebellum is that of "an ellipsoid flattened from above downwards."* Its principal diameter, which is transverse, is from three-and-a-half to four inches in length; the antero-posterior diameter is from two inches to two inches and a half; the anterior part is about two inches in thickness; whilst near its posterior edge it does not measure above half an inch.

At its anterior edge the cerebellum is notched, and receives fibres by which it is connected to the cerebrum and mesocephale. This notch is of considerable transverse extent, and is semilunar in shape. The greater portion of the posterior part of the mesocephale corresponds to it. By Reil this is called the *semilunar fissure.* In it we find several parts which the anatomist should study; namely, on the highest plane, the processus cerebelli ad testes, sepa-

* Cruveilhier.

Fig. 389.

n, the flock on the right side, or lobule of the vagus.

5, fifth nerve. On the left side a layer appears to be extended from this nerve which contributes to form the crus cerebelli.

rated by the valve of Vieussens, and, beneath these, the fibres of the restiform columns, and the right and left extremities of the pons Varolii, all of which combine to form the crus cerebelli or central stem of each lateral lobe.

The posterior margin is interrupted in its middle by a vertical notch, which divides it into a right and left portion. This notch is wider in front than behind, whence Reil called it the *purse-like fissure*. The term *posterior notch* is preferable. It receives the falx cerebelli, and at its bottom we observe a continuity between the superior and inferior laminæ of the median lobe of the cerebellum.

The superior surface of the cerebellum is slightly convex, inclined backwards and downwards. It terminates in front by a concave margin, which overlaps the parts contained in the semilunar fissure. This surface is more convex along the middle than on either side. In the latter situations it is inclined and nearly plane; but in the former it resembles more the surface of a cylinder. This middle portion corresponds to what is commonly called *the superior vermiform process*: it is in fact the upper surface of the median lobe of the cerebellum.

On its inferior surface the subdivision of the cerebellum into two symmetrical portions is very apparent, by reason of the existence of a deep fissure which proceeds from before backwards along the median line, and is continuous behind with the posterior notch. This fissure is called the *valley (vallecula*, Haller; *grande scissure mediane du cervelet)*. It separates the hemispheres of the cerebellum, each of which presents a very convex surface, corresponding to each occipital fossa. The arachnoid membrane is extended from one to the other, towards the posterior part of the fissure, leaving a considerable space between it and the pia mater, which is traversed by some fine bundles of fibrous tissue and occupied by subarachnoid fluid. This space has already been referred to as the *posterior conflux* of Majendie.

The anterior part of this fissure receives the upper and posterior portion of the medulla oblongata. The remainder of it is occupied by the inferior surface of the median lobe of the cerebellum, presenting a remarkable cruciform arrangement, which will be presently described.

Another very remarkable fissure requires a special notice. It is horizontal, and passes into the substance of the cerebellum, dividing it into an upper and an inferior portion. By inserting the handle of a knife along the posterior margin of the cerebellum, this fissure may be shewn to pass forwards to a considerable depth, and to communicate on each side with the semilunar fissure, whilst it is interrupted in the middle posteriorly, by the notch. Its inner surface is lined by a process of pia mater, which sinks into it.

The right and left cerebellar hemispheres exhibit a general symmetry, which is, however, not always perfect, as a manifest difference is sometimes observable in their sizes. And a corresponding want of symmetry may be frequently seen in the right and left fossæ of the occipital bone.

Both the hemispheres and the median lobe are composed of an assemblage of laminæ closely applied to each other. Each lamina consists of a thin layer of white or fibrous matter, between two of grey or vesicular substance, which are continuous along the outer margin of the former. Thus the exterior of the cerebellum consists of a stratum of vesicular matter, which forms a cortex to the enclosed white or fibrous substance. The laminæ are separated from each other by fissures, and they are covered by pia mater, which adheres closely to them, and penetrates to the floors of the fissures.

The laminæ are collected into sets on the superior as well as on the inferior surface. Each set forms a lobe. Each lobe is surrounded by a deep fissure, which separates it from the next adjacent lobes.

It is necessary to distinguish the fissures which separate the laminæ from those by which the lobes are bounded. The former are very shallow: the latter are deep, and penetrate quite to the central stem of the hemisphere.

By removing the pia mater carefully from the surface of the hemispheres, and from the deep fissures, the shape and boundaries of the lobes may be clearly demonstrated. Or if a vertical section of a hemisphere be made, the deep fissures may be readily distinguished from the superficial ones which separate the laminæ; and in this way also the lobes may be demonstrated.

The floor of each deep fissure is formed by white matter. And as the deep fissures intervene between the lobes, laminæ of the lobes constitute their walls, and the superficial fissures which separate these laminæ open into them.

On the superior surface of the cerebellum two principal lobes may be distinguished. These are *the square lobe* and the *posterior superior* lobe, according to the nomenclature of Reil, whose descriptions cannot be surpassed in minuteness or accuracy. (*Fig.* 390, A, P.)

The anterior margin of the square lobe overhangs the semilunar fissure; its posterior margin is a little behind the level of the floor of the posterior notch. By careful separation of its laminæ or by a vertical section, it may be shewn to consist of eight lobules, each having a stem of fibrous matter derived from the central one of the hemisphere.

The posterior superior lobe (P, *fig.* 390,) forms the posterior part of the superior surface of the cerebellum; its posterior margin is that of the hemisphere; the horizontal fissure separates it from the posterior inferior lobe. It is separated from its fellow of the opposite side by the posterior notch.

On the inferior surface of each hemisphere the following lobes are readily distinguishable. (*Fig.* 391.) We enumerate them, passing from before backwards.

1. *The amygdala,* so called from its resemblance to an enlarged tonsil. This and its fellow of the opposite side form the lateral boundaries of the anterior extremity of the valley, and are in great part covered by the medulla oblongata.

2. Behind the amygdala is the *biventral lobe*, wedge-shaped, narrow towards the valley, wide towards the semilunar fissure. Its laminæ are curved with their concavity forwards and inwards, and it is united with its fellow of the opposite side by laminæ which cross the valley forming part of the inferior vermiform process.

3. The *slender* lobe, which consists of a few laminæ curved parallel to the posterior ones of the biventral lobe.

4. The *inferior and posterior* lobe, which extends to the posterior edge of the hemisphere. The inner margin of each of these lobes constitutes the lateral boundaries of the posterior notch.

Such is the constant disposition of the superior and inferior surfaces of the cerebellum. A defect of symmetry is sometimes apparent in the inequality of corresponding lobes; but those above enumerated are always present. So definite an arrangement must obviously have some physiological import. What that may be it is impossible even to conjecture, and we must be, for the present, content with a concise statement of the facts of the anatomy. Some analogy exists between this arrangement and that of the convolutions on the surface of the brain, many of which exhibit a constancy of position and form quite as remarkable.

The median portion of the cerebellum is also composed of laminæ, which are continuous with those of the hemispheres, but their arrangement on the superior and inferior surfaces is so different as to demand a separate description. On the superior surface the laminæ are separated from each other by fissures, in the same way as those which constitute the hemispheres, and they are collected into sets forming lobes which correspond to and connect those of the lateral hemispheres. These laminæ are curved, their anterior margin being very slightly convex (*fig.* 390). The edges of these laminæ, as they lie in close apposition, resemble the segments or rings of a worm; whence the term *vermiform* has been applied to this as well as the inferior surface of the median lobe. The laminæ take for the most part a vertical direction, with the exception of the anterior and posterior ones, which pass gradually to the horizontal, the free margins of the former being directed forwards and those of the latter backwards. The pos-

Fig. 390.

terior laminæ form the floor of the posterior notch: the anterior form, by their adhesion to each other, the layer known by the name of *valve of Vieussens*, which fills up the interval between the *processus cerebelli ad testes*.

The laminæ which form the superior surface of the median lobe, (or the superior vermiform process,) are considerably fewer than those of the hemispheres. This explains the less depth of the median lobe, when measured from before backwards, than of the hemispheres. Two or more of the laminæ of the latter are united to a single lamina of the former, and thus the superior vermiform process serves as a transverse commissure to the superior laminæ of the hemispheres.

The inferior surface of the median lobe, or *inferior vermiform process*, is likewise composed of laminæ, which take a transverse direction and present a free convex border, with some resemblance to the rings of a worm in action. (*Fig.* 391.) These laminæ are not all of equal transverse extent. The middle and posterior are the broadest; the anterior gradually diminish in size. Hence the body which results from the conjunction of all the laminæ has a triangular form, its apex being anterior and its base posterior, corresponding to the notch between the hemispheres. The laminæ which occupy its middle have a greater depth than the rest, and consequently the body is more prominent at this situation.

Certain deep fissures divide the inferior vermiform process into segments which evidently correspond with and connect the lobes into which the hemispheres are subdivided on their inferior surface.

These segments may be very readily distinguished from each other, and the names which the accurate Reil has given them are sufficiently appropriate. By separating each segment from the adjacent ones and tracing its lateral relations, the anatomist may form a better idea than by any other means of the way in which this portion of the cerebellum is connected with the hemispheres.

The anterior extremity of the inferior vermiform process projects into the cavity of the fourth ventricle, and serves to close it at its inferior extremity. It is a pointed process, furrowed transversely, continuous by its base with the rest of the vermiform process. Reil has named it *the Nodule*. From either side of it a valve-like membrane of exquisite delicacy extends forwards and outwards towards a lobule which is attached to each crus cerebelli near to the origin of the auditory nerve. These membranes resemble very much in shape the semilunar valves of the aorta. By their attached margin they adhere to the crus cerebelli, and their free margin projects into the cavity of the fourth ventricle. Their inner extremities adhere to the nodule, and are connected to each other by a thin membrane of precisely similar texture, which is a commissure to them. Reil gives to the two membranes and their intermediate connecting one the name of *posterior medullary velum*.* The lateral membranes were first de-

* The valve of Vieussens is the anterior medullary velum.

scribed by Tarin and Malacarne. When the fourth ventricle has been carefully opened in a recent cerebellum, it is very easy to demonstrate them by passing the handle of a knife under them.

The structure of these lateral wings of the inferior medullary velum is readily ascertained. Their delicacy is such that they admit of being examined by the microscope without pressure or other manipulation. They consist of tubular fibres of various sizes, taking a transverse direction, that, namely, of the long diameter of each wing, covered by a layer of nucleus-like particles as an epithelium. They seem to connect the nodule to the small lobules of the pneumo-gastric nerve above mentioned (the *flocks* of Reil), or to connect those lobules themselves as a commissure.*

The nodule pushes before it, into the fourth ventricle, a fold of the pia mater, connected with which on either side are several small granulations, or *Pacchionian bodies*. It is called *the choroid plexus* of the fourth ventricle. We can easily trace it to be continuous with the pia mater which covers the lobules of the seventh pair of nerves.

Next to the nodule, below and behind it, is a small lobe, called by Reil the *spigot (Zapfen)*, with a pointed extremity directed downwards and forwards. It consists of several small laminæ separated by their fissures. Behind it is a larger lobule, which forms the most prominent portion of the inferior vermiform process, called by Reil, from its form, the *pyramid*. Its apex is directed downwards and backwards, and it likewise consists of numerous small laminæ.

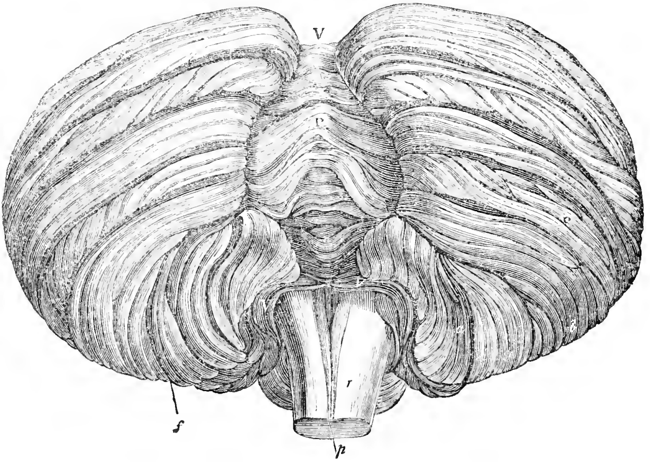
These lobules of the inferior portion of the median lobe serve to connect others of the lateral hemispheres. The *spigot* connects the almond-like lobes; the *pyramid* the biventral and the slender lobes.

Posterior to the pyramid are a series of laminæ which extend to the posterior notch and form its floor. These pass directly from one side to the other, their free margin being convex and directed backwards. They connect the posterior inferior lobes. And some of the most anterior of them, which do not project to the surface, connect the slender lobes as well as some of the anterior laminæ of the posterior inferior lobes. These latter laminæ of the inferior vermiform process, Reil distinguishes by the name of *long* and *hidden commissure (langen verdeckten Commissur)*, and the former constitute his *short and exposed commissure (Kurzen und sichtbaren Commissur)*.

Above the last-named commissure is a single lamina which forms a line of demarcation between the inferior and the superior vermiform processes, serving to connect the upper and posterior lobes of the hemispheres. This is *the single commissure (einfache quer Commissur)*.

It will serve to elucidate the foregoing necessarily intricate description, if I sum up with

Fig. 391.



Inferior surface of the cerebellum.

V, inferior vermiform process; *p*, posterior pyramids; *r*, restiform bodies.

the following enumeration of the lobes of the hemispheres, specifying at the same time the commissures by which they are connected, i. e. the lobes of the superior and inferior vermiform processes which serve that purpose.

1. On the superior surface of the hemispheres.

a. The square lobes, consisting of eight lobules, which are connected by as many, or nearly so, of the superior vermiform process.

* Although it does not appear that Reil used the microscope, his statement respecting the structure of these wings is perfectly correct.

b. The upper and posterior lobes, connected by the single commissure, to be sought for on the floor of the posterior notch.

2. On the inferior surface of the hemispheres.

a. The amygdalæ, united by the spigot.

b. The biventral lobes.

c. The slender lobes.

The biventral lobes and the anterior laminæ of the slender lobes are united by the pyramid.

d. The posterior inferior lobes, connected by the short and exposed and the long and hidden commissures.

The flocks or lobules of the pneumogastric nerve, (*lobule of the auditory nerve*, Foville,) which are situate altogether anterior to the hemispheres and attached to each crus, are united by the posterior medullary velum, and through it appear to have some connection with the most anterior portion of the inferior vermiform process.

A vertical section of either hemisphere of the cerebellum or of its median lobe displays its structure, and serves further to demonstrate the subdivision into lobes above described. When either hemisphere is cut in the vertical direction, the surface of the section displays a beautiful ramification of fibrous matter, the smaller branches of which are enveloped by laminæ of grey matter. This appearance has such a resemblance to the trunk of a tree with its boughs and branches, that it early received and has continued to retain the name of *arbor vitæ*. The trunk of the tree is represented by a central nucleus of white matter, from the upper and lower surfaces of which branch off, some at a right, others at an acute angle, several laminæ, each of which forms the parent stem of a number of other branches. Each of the primary branches is the foundation or central stem of a lobule. Laminæ of fibrous matter are seen branching from both sides of it immediately after its separation from the nucleus. Sometimes the primary branch bifurcates, and each division of it forms the stem of what may be called a sub-lobule. The ultimate branchings are covered by a layer of grey matter. If we suppose that one of the primary branches is composed of a certain number of laminæ of fibrous matter, the secondary ramifications from it will in a great degree correspond. In most instances these secondary branches subdivide into two or more tertiary ones, which, as well as the branch from which they spring, are enclosed in grey matter. (*Figs.* 380, 386.)

A vertical section of the median lobe gives quite a similar appearance to that of the hemispheres. The central nucleus breaks up into primary branches, which become the centre of the lobules of which it consists. (*Figs.* 386, 393.)

The ramifications of the central nucleus, whether of the median lobe or of the hemispheres, separate from it only in the vertical plane or from before backwards; in the latter direction, however, to a very slight extent. Hence these branches are directed only upwards, or downwards, or backwards. The fibrous matter of the median lobe is continuous, without any line of demarcation, with that of the hemispheric lobules. By reason of this disposition of the fibrous matter, the surface which is exposed by a horizontal section through the entire cerebellum, presents a very different appearance from that which results from a vertical section. It consists of a plane of fibrous matter bounded on the sides and behind by a narrow cortex of grey matter.

The white matter consists exclusively of fibres, chiefly of the tubular kind and of all degrees of size. These, in the more distant ramifications, penetrate the vesicular matter of their grey cortex, and form some unknown connection with its elements. The grey matter consists of three layers, readily distinguishable by the naked eye from their difference of colour. The external layer is the darkest, and consists chiefly of granular and vesicular matter. The next or intermediate layer is of a light colour, and is composed of a stratum of fine nucleus-like particles. The third layer has the greatest thickness, and is immediately in contact with the fibrous matter; it is intermediate in point of colour to the other two, and consists of numerous vesicles of the caudate kind, especially with branching processes and nerve-tubes of all sizes. The dark colour of the external layer is doubtless owing in a great measure to the great numbers of capillary vessels which enter it; the greater paleness of the inner stratum is to be attributed to the intermixture of the white fibres, whilst the light colour of the middle stratum is intrinsic. From the usual dependent position of the cerebellum in the dead body, it always appears to contain more blood than the cerebrum.

Corpus dentatum.—If, in making a vertical section of either hemisphere of the cerebellum, the incision be made so as to leave two-thirds of the hemisphere on its outside, a peculiarity will be observed on the surface of the section which deserves a separate consideration. The central white nucleus is interrupted by a very remarkable undulating line of vesicular matter, which is convex towards the posterior margin of the hemisphere, but open in front towards the crus cerebelli.

This constitutes the *corpus dentatum* or *rhomboideum* of the cerebellum. It presents a remarkable resemblance to the structure of the same name which is met with in the olivary body of the medulla oblongata. It is evidently a capsule of vesicular matter which is enclosed in the inner third of the substance of the central white nucleus of the cerebellar hemisphere, being nearer its superior than its inferior surface. The peculiar undulating arrangement of it doubtless has reference to the accommodation of a certain extent of surface in a limited space. The fibrous matter enclosed by it seems derived from the processus cerebélli and from the restiform body.

The central stem of fibrous matter to which the several lobules, both of the hemispheres and the median lobe of the cerebellum, adhere, (*crus cerebelli,*) is formed by three bundles of fibres, each situate on a different plane. These are the *peduncles* of the *crus cerebelli.* Through them the cerebellum forms a connection with other parts of the encephalon. The superior layer or peduncle is a bundle of fibres which extends to the corpora quadrigemina, and may be traced beneath them to the optic thalami. These are the *processus cerebelli ad testes*, but from their being obviously a medium of connection between the cerebellum and the cerebrum, they may be better named *cerebro-cerebellar commissures.* It is worthy of remark, that these are the only fibres which appear to connect these two segments of the brain. The middle layer is continuous with the restiform bodies, *processus cerebelli ad medullam oblongatam.* And the inferior layer is evidently derived from the transverse fibres of the pons Varolii, which thus pass from one hemisphere to the other, and constitute a great commissure to the cerebellar hemispheres. These fibres, moreover, connect each hemisphere to the mesocephale (*fig.* 380, *t, r, v*).

From this triple constitution of the crus cerebelli, it is plain that the cerebellum may exert an influence upon, or be affected by the optic thalami or quadrigeminal bodies, the restiform columns, or the mesocephale.

Of the fourth ventricle.—This is a rhomboidal cavity, situated at the upper and posterior part of the medulla oblongata, and extending over part of the superior surface of the mesocephale. It is limited superiorly by the posterior margin of the testes, and inferiorly by the superior blunt extremity of the posterior pyramids. Its two lateral angles correspond to the entrance of the restiform bodies into the crura cerebelli. In fact, it is formed by the divergence of the restiform columns in their ascent to the hemispheres of the cerebellum. The median lobe of the cerebellum lies over the fourth ventricle, and conceals it from view. The anterior lobule of the inferior vermiform process, *the nodule*, projects into it, and closes it below. On either side of this lobule a process of pia mater, with small granulations upon it, is found. These processes are the *choroid plexuses* of the fourth ventricle. Around these and thence on to the nodule, the proper membrane of the ventricle is reflected, and thus its cavity is shut out from any communication with the subarachnoid cavity. A vertical section in the median plane, or a little to one side of it, displays this arrangement well. (*Fig.* 392.)

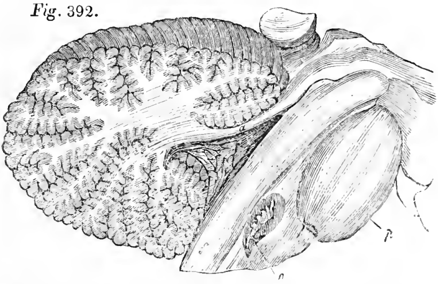
Along the floor of the fourth ventricle we find the central or olivary columns of the medulla oblongata extending upwards to the optic thalami. A fissure, continuous with the posterior median fissure, separates these columns, and terminates above in a canal which penetrates the mesocephale, to reach the third ventricle: *iter a tertio ad quartum ventriculum* or *aqueduct of Sylvius.* On either side of the fissure certain bundles of white fibres, continuous with the auditory nerves, join it at right angles, crossing over the olivary columns. This fissure, with its white fibres on each side, has been compared to a pen with its barbs, and hence called *calamus scriptorius.*

The fourth ventricle, although sometimes called the ventricle of the cerebellum, properly belongs to the medulla oblongata. It is present in all the vertebrate classes, and in size bears a direct proportion to that of the medulla itself.

OF THE HEMISPHERES OF THE BRAIN.—A mass of fibrous matter, covered on its exterior by a convoluted layer of vesicular matter, inflected towards the mesial plane above and below a pair of gangliform bodies, (*optic thalami* and *corpora striata,*) which it thus encloses in a cavity or ventricle—this, with certain fibres connecting its anterior to its posterior parts, forms a cerebral hemisphere. The hemispheres of opposite sides are applied to one another along the mesial plane, leaving the fissure-like interval called the third ventricle; and they are united by a plane of transverse fibres, the greater part of which is placed above that ventricle, but which bends down anteriorly as well as posteriorly, closing the fissure at those situations.

Of the convolutions.—That which first attracts attention in connection with the cerebral hemispheres, as affording the highest physiological as well as anatomical interest, is their convoluted surface. This can only be well displayed by stripping off the pia mater. The appearance which is then presented has been variously described by different writers. It has always seemed to me to resemble the folded surface formed by the mucous membrane of the stomach when the muscular coat is very much contracted. The rugæ of that membrane become enormously developed by the excessive contraction of the muscular coat: the mucous membrane not possessing any contractile power is thrown into thin folds to adapt it to the diminished capacity of the stomach. Its folded state indicates a great disproportion between the extent of the mucous surface and that of the muscular tunic. If both

Fig. 392.



Vertical section of the median lobe of cerebellum, mesocephale, and medulla oblongata, to shew the fourth ventricle.

o, corpus dentatum; *f*, posterior surface of medulla oblongata; *p*, pons Varolii; *a*, processus cerebelli ad testes; *v*, cavity of the fourth ventricle.

surfaces were equal, neither of them would be thrown into folds. In examining the surface called *centrum ovale*, which is exposed by a horizontal section through the hemisphere above the level of the corpus callosum, we obtain an explanation of the formation of the convoluted surface of the brain. That plane of fibrous matter is surrounded by an undulating margin of vesicular matter, the foldings of which give rise to the convoluted appearance of the cerebral surface. The fibrous matter is adapted to this irregular surface, not by any similar folding, but by the prolongation of its fibres into the concavities of the folds. It is only by means of these prolongations that an equality obtains between the surface of grey matter and that of fibrous matter which it covers. In brains devoid of convolutions, the vesicular and fibrous surfaces are applied to each other as two layers disposed in concentric circles. There are no irregularities in either one or the other. But any increase in the extent of the grey surface involves a corresponding complication in that of the fibrous matter, which is effected by the prolongation of the fibres at certain situations. Were we to suppose two brains in which the quantity of fibrous matter in the hemispheres was equal, the quantity of grey matter in one might be increased considerably, and therefore become convoluted without involving any other alteration in the fibrous matter than the elongation of certain bundles of fibres at particular situations.

The existence of convolutions on the surface of the hemispheres, as contrasted with the absence of them, indicates an increase in the developement of the dynamic matter. A convoluted brain, even although actually smaller than one with a smooth surface, would yet indicate a higher degree of mental power, inasmuch as it possesses a larger quantity of the vesicular matter relatively to its fibrous matter.

Cerebral convolutions are wanting in all the classes below Mammalia. They are likewise absent from the brains of many animals of the families Rodentia, Cheiroptera, Insectivora, some of the Marsupialia, and Monotremata. The brains of these Mammalia resemble very closely, as regards the characters of the cerebral hemispheres, the brain of Birds. There is not a trace of a convolution upon them, and the only fissure is the imperfectly developed one of Sylvius. The squirrel, the bat, the mole afford examples of brains deficient in convolutions. In some genera of the families Insectivora and Marsupialia, however, we find an approach to the convoluted cerebral surface in certain depressions marked on the exterior of each hemisphere. The fissure of Sylvius is more developed, and certain depressions, taking for the most part a longitudinal course, are seen on the surface of each hemisphere. The brains

Fig. 393.

Vertical section of the adult human brain. (After Arnold.)

The position of the internal convolution with reference to the corpus callosum is well displayed. The median lobe of the cerebellum has been cut through, and the fourth ventricle exposed. *a, a, a*, internal convolution, (*d'ourlet*, Foville); *c*, corpus callosum; *o*, fornix; *n*, septum lucidum; *f*, pineal body; *i*, anterior commissure; *h*, hypophysis, or pituitary body; *t*, pons Varolii; II, second pair or optic nerves; IV, fourth ventricle.

Superior surface of the right hemisphere of the adult human brain.

The undulating form of many of the convolutions is very well seen, and the general characters of the convoluted surface are displayed.

of the rabbit, the beaver, the guinea-pig, the agouti shew these fissures. They are generally regular in different individuals of the same genus, and they are symmetrical, i. e., of the same length and direction, and occupy the same place on each hemisphere.

Leuret remarks, in reference to the dogma of Gall and Spurzheim, that the presence and number of the convolutions are in direct relation to the volume of the brain, that such is far from being universally the case; and I am glad to refer to so excellent an authority in confirmation of the view which I have advocated respecting the true signification of the cerebral convolutions. According to this anatomist, the ferret, which has several well-marked convolutions on each hemisphere, has a brain no larger than that of the squirrel, which is entirely devoid of them, and which has not even the few fissures which faintly indicate their first developement in the brains of the rabbit, the beaver, the agouti, &c. And these animals last named have the brain actually *larger* than that of the cat, the pole-cat, the roussette, *(Pteropus vulgaris,)* the unau, *(Bradypus didactylus,)* the sloth, *(Bradypus tridactylus,)* and the pangolin, all of which possess convolutions.

All mammiferous animals, excepting those mentioned in the preceding paragraphs, have convolutions which exhibit more or less of complication. This complication has evidently no connection with the general organization of the animal, inasmuch as we find animals, in the same family with those which possess numerous convolutions, exhibiting a very slight developement of them. The monkeys, the dolphin, the elephant, exhibit the most numerous convolutions of any of the Mammalia inferior to man, in whose brain the convoluted surface reaches its highest point.

Each fold on the surface of the brain is ordinarily called *a convolution*, whatever be its position, size, or direction. It consists of a fold of grey matter, enclosing a process of white or fibrous matter. On each side of it is a sulcus or groove, in which we find the same elements, a fold of grey or vesicular matter—concave externally, convex internally — the fibrous matter adhering to its convex surface. As the convolution exhibits no essential difference of structure from the sulcus, it is plain that the former portion of the brain's surface cannot differ in physiological office from the latter. We describe particular convolutions, not because they are to be regarded as endowed with special functions distinct from the less prominent portions of the cerebral surface, the sulci, which are continuous and identical in structure with them, but because they afford good indications of a particular arrangement of the surface of the hemispheres by which one brain may be coveniently compared with another, whether they belong to the same or to different groups of animals.

The folded arrangement of the surface of the hemispheres, dependent as it is upon the grey matter, is evidently destined to bring the central and deep-seated parts of the hemispheres into union with a large extent of vesicular surface.

That the disposition of the convolutions, like that of all other parts of animal bodies, follows a particular law, is well illustrated by comparing the brains of different groups of animals, in their gradation from the more simple to the more complex.

M. Leuret very justly makes a distinction between those convolutions which are constant, and to be found throughout the whole series of convoluted brains, occupying the same position, and differing only in size and extent of connections, and those which are not constant, even in the brains of the same group of animals, but are dependent on the extent of the primary ones, and the connections which they form with others near them. According to this idea we may classify the convolutions as *primary* and *secondary*.

The primary convolutions are all formed after one type. Of this, as M. Leuret suggests, the brain of the fox may be taken as the basis. The fissure of Sylvius is well marked in this brain; it is bounded by a prominent convolution, which encloses it above, below, and behind—thus forming a curve, the concavity of which is directed forwards and downwards. Above and behind this we find a second convolution forming a similar curve and parallel to the first. It exhibits a slight undulation, and is marked by a short fissure—signs of advancing complication. Still further back and upwards there is a third convolution, parallel and curved similarly to the second; this bifurcates at one point. Above all, near the summit of the hemisphere, a fourth is found disposed in the same curved manner, but exhibiting some sinuosities or undulations at its anterior portion. A fifth convolution exists on the inferior surface of the anterior lobe and rests upon the roof of the orbit. Leuret designates it *the supra-orbitar convolution*. The sixth convolution is of great extent; the principal portion of it is found on the inner surface of each hemisphere above the corpus callosum; in front it bends downwards and backwards to the fissure of Sylvius, and behind it extends to the middle lobe and forms the hippocampus major. This convolution exists in a high state of developement in the human brain, and has attracted very generally the attention of anatomists. Foville describes it by the name *convolution d'ourlet*.

Such is the most simple arrangement of the convolutions. The complication of this takes place by undulations being formed in the convolutions themselves, by a subdivision of them at certain situations, by the junction of neighbouring ones through smaller folds crossing the sulci between them, and in the highest classes by the addition of totally new convolutions.

Animals, whose brains have nearly the same degree of developement as that of the fox, have exactly the same convolutions, differing, however, somewhat in point of size. This increase of size is denoted by undulations formed in the course of convolutions throughout more or less of their extent. The dog may be taken as an example. M. Leuret states that, in comparing the brains of several dogs together, he found with all of them the same convolutions, differing only in the extent of undulations and the number of depressions, both of which were greatest in the largest brains. The brain of a large mastiff *(chien dogue)*, a good watch-dog, of such great ferocity that he attacked the person who fed him, had all the convolutions very large and much undulated, with numerous depressions in them.

A group of animals, consisting of the cats and the hyena, exhibits another stage of increase in the developement of convolutions. The same type prevails as in the fox and dog; four external convolutions, one internal, and a supra-orbitar. These convolutions, however, are united to each other at numerous points by means of small folds crossing the sulci. These uniting folds form the *secondary* or *supplementary* convolutions. Nearly all the primary convolutions have supplementary ones connected with them.

A group, which includes the sheep and other ruminant animals, exhibits much more complication in the cerebral convolutions, but still preserves the same type. The undulations and the supplementary convolutions are more numerous. The primary appear less numerous because less distinct. The anterior part of the internal convolution is much increased in developement, and the supra-orbitar is much more complex. In the fissure of Sylvius some small convolutions are found which are the first developement of those which in the human subject constitute the *insula* of Reil.

In the brain of the elephant new convolutions are added. These consist of folds passing in a perpendicular direction; the primitive convolutions always taking a longitudinal course. These latter are divided by the former into an anterior and a posterior set. Others are found above and in front of the fissure of Sylvius; three superior convolutions are found, the continuations of which backwards are situate above the internal convolution. All the convolutions of the elephant are remarkably undulating and exhibit numerous depressions. The brain of the whale is very similar to it in this respect, and both resemble that of man.

Monkeys have not the tortuous or complicated convolutions which are found in the whale and elephant. Yet the developement of the hemispheres at their posterior part, the general form of the brain, the extent and inclination of the fissure of Sylvius approximate the brain of monkeys to that of man much more nearly than the whale's or elephant's, which, notwithstanding their complicated convolutions, are generally inferior in organization, and resemble the brains of other Mammalia. The internal convolution in monkeys is simple; below and behind it forms the hippocampus, from which convolutions are prolonged backwards, forming the posterior lobe. Two superior convolutions are met with above the fissure of Sylvius, between which is placed a transverse fissure very constant, called the fissure of Rolando. The orbitar convolutions are largely developed.

In comparing the human brain with that of the inferior animals, we notice great exactness of symmetry between the convolutions of opposite hemispheres in the latter, and the want of it in the former. It cannot, however, be said that the convolutions of opposite hemispheres in the human subject are absolutely unsymmetrical. A careful examination will show that the same convolutions exist on each side, but apparently of different sizes, and not closely corresponding as regards situation. My meaning will be more readily understood by referring to *fig.* 381, p. 671, where the same numbers have been affixed to corresponding convolutions. No. 1 on the right has a certain general resemblance with No. 1 on the left, which would be much more perfect but for the fissure which marks the convolution of the right hemisphere. Again, Nos. 2, on opposite sides, resemble each other so closely that their symmetrical relation cannot be doubted. The likeness, however, is impaired by slight fissures in the convolution on the left which do not exist in that on the right side. Nos. 3 and 3 evidently correspond, but that of the right side is the larger and more undulating. And it may here be remarked that this great developement of the convolution marked 3 on the right side affects materially the position, relations, and shape of those in its neighbourhood, by throwing them backwards or outwards and altering their form. Thus the position and shape of convolution 4 seems evidently modified by the large posterior undulations of convolution 3. In the brain from which the figure was taken, the convolutions on the right side are evidently larger and more highly developed than those of the left. It does not appear that there is any constancy with respect to the relative size of the convolutions of the right and left side, sometimes one side predominating, sometimes the other; nor have we any clue to discover the cause of the difference between the two hemispheres, or the reason of the variation as regards predominance of size.

In the imperfectly developed brains of the infant or young child, the convolutions are quite symmetrical. They are so likewise in idiots, or persons of very inferior intellect, and, as has been already stated, in some Negro brains.

The following convolutions of the human brain are constant in their position, although they differ much in different brains in size and developement.

1. *The internal convolution,* or that of the corpus callosum, called by Foville *convolution d'ourlet (processo cristato,* Rolando). The principal portion of this convolution is above and parallel to the corpus callosum: in front it curves down parallel to the anterior reflection of the corpus callosum, as far as the locus perforatus, connecting itself with some of the anterior convolutions. Behind it passes in a similar manner round the posterior reflexion, connecting itself with some of the posterior convolutions, and in the middle lobe forming the hippocampus major, the anterior extremity of which is situate immediately behind the fissure of Sylvius and locus perforatus. Its horizontal portion appears to be connected with some nearly vertical ones, which seem indeed to branch off from it. *(Fig.* 395, O.)

This is the most constant and regular convolution of the brain. It exhibits with its fellow of the opposite side very exact symmetry. Its inferior or concave border is smooth and uninterrupted, and forms the superior boundary of a sulcus, which intervenes between it and the surface of the corpus callosum. It forms, to use Foville's expression, a hem or selvage to the cortical layer of the cerebral hemisphere. The fibrous matter which is inclosed by the cortical layer of this convolution consists of longitudinal fibres following the same general direction, a large number of them no doubt bending inwards into the cortical layer. These fibres are evidently commissural in their office, and will be referred to by-and-bye as constituting the *superior longitudinal commissure.*

The free margin of this convolution varies in

Fig. 395.

The fibres of the internal convolution are seen in the middle lobe extending to the hippocampus major.

its characters in different brains, according to the degree of tortuosity it exhibits, and the number of small fissures which are met with in it. The small folds which connect it with other convolutions on the inner surface of the hemisphere vary in number, and are generally found most numerous at its posterior part. Some of these folds are not distinctly visible unless the sulcus above it has been freely opened, as they are situated quite on its floor.

2. *The convolution of the Sylvian fissure.*—This convolution forms the immediate boundary of this great fissure. We have seen its early developement in the simple brain of the fox, and we may observe it gradually rising in complexity through all the intermediate stages up to the most highly developed brains. In the elephant it is remarkably tortuous, and is connected anteriorly as well as posteriorly with convolutions which pass to the anterior and superior and to the posterior part of the brain.* In man it is also very tortuous, and the numerous folds which pass from it forwards or backwards, forming primary or secondary convolutions, render it difficult to isolate it sufficiently for the anatomist to follow it throughout its entire course. Its inner border is likewise interrupted by the connections which it forms with the convolutions of the floor of the Sylvian fissure.

3. Within the fissure of Sylvius we find that remarkable group of convolutions called by Reil *insula*, the island. It consists of a series of small folds radiating from a common centre and connected with the convolution last described by still smaller folds, which cannot be seen unless when the fissure has been very freely laid open. The centre from which the convolutions radiate is the apex of a cone, the base of which adheres to the floor of the fissure.

4. On the inferior surface of the anterior lobe there is a pair of longitudinal convolutions which enclose between them the fissure of the olfactory process. The external of these convolutions is continuous with the convolution of the Sylvian fissure.

The numerous secondary convolutions which are found over the surfaces of the brain render it difficult to distinguish the primary ones. These latter are indicated by the antero-posterior course which they take—the former being more or less vertical. The largest and most tortuous convolutions are found on that part of the external surface which corresponds to the parietal bone. Next to them, in point of size, are the convolutions of the anterior lobe, but the smallest of all are those of the posterior lobes.

The hippocampi, major and minor, are constant convolutions, which project into the lateral ventricles, the latter into its posterior, the former into its descending horn.

In general the constituent fibres of the white matter of the convolutions converge from the inner surface of the cortical layer to the centrum ovale, or if followed from the centrum ovale, they radiate to the grey surface, whether of a convolution or of a sulcus. A remarkable exception is in the case of the internal convolution, the fibrous matter of which constitutes, as has been already explained, a longitudinal commissure. The thickness of the cortical layer is pretty uniform, at least relatively to the size of the folds themselves. Throughout its entire thickness it is mixed with fibres, which are most numerous at its adherent surface, but extremely few and scattered at its free surface.

In hydrocephalus the convolutions disappear. The fibrous matter becomes greatly expanded by the fluid accumulated in the ventricles, and when its expansion has gone so far as to equal the grey surface, the folded character of the latter disappears. This takes place precisely in the same way that the rugæ of the contracted stomach (as before referred to) become obliterated when the muscular coat relaxes and allows the full distension of the organ.

Mayo supposes that other fibres are found in the convolutions besides those which are continued into the centrum ovale. These are commissural ones, which pass from convolution to convolution—either between adjacent or distant ones—forming arches the convexities of which are directed to the centrum ovale. I have never succeeded in satisfying myself of the existence of such fibres either in the fresh brain or in that preserved in spirit. If they exist, it is evident that they must be commissural between particular convolutions. The same anatomist supposes that similar commissural fibres connect the laminæ of the cerebellum.

The principal bulk of the hemispheres is formed by fibrous substance. This is shown by the horizontal section which displays the centrum ovale. These fibres radiate from those surfaces of the optic thalami and corpora striata which are in contact with the substance of the hemisphere. Most of the fibres which emerge from these gangliform bodies pass to the grey matter of the convolutions. Some, however, turn inwards towards the mesial plane, and form the corpus callosum by their union with those of the opposite side.

It cannot be supposed that all the remaining fibres, after subtracting those which form the corpus callosum, pass through the thalami and corpora striata. The disproportion of number between the fibres of the medulla oblongata and these is too striking to allow such an hypothesis. They mingle with the vesicular matter of both; some do not pass beyond them; others are continued into the medulla oblongata, either to its olivary or its pyramidal columns.

Corpora striata and optic thalami.—The corpora striata and optic thalami bear a strong resemblance in general character and structure to ganglia. They are ovoid masses placed between the fibrous substance of the hemisphere on the one hand, and the medulla oblongata on the other. These bodies, which are best displayed by laying open the lateral ventricle (p. 675), are very closely united to each other. The corpus striatum is placed a little in front

* See Leuret, pl. xiv. representing the external surface of the elephant's brain.

and to the outside of the thalamus. It is pear-shaped: its thick end is directed forwards and inwards, and it gradually tapers backwards into a caudate process of considerable length, which winds downwards, forwards, and inwards into the descending cornu of the lateral ventricle, at the anterior extremity of which it terminates. Placed on the outside of the thalamus, it seems to embrace it there, and to adhere very intimately to it. The tænia semicircularis lies in a groove between the two bodies, and as it were constricts their connecting fibres.

The corpus striatum is of a dark grey colour. A considerable portion of it projects free into the cavity of the ventricle, forming an extensive convex surface there. The rest is firmly imbedded in the fibrous substance of the hemisphere, and in position corresponds to the base of the insula, which for that reason has been called *the lobule of the corpus striatum*. The free surface as contributing to form the ventricular wall is covered by the lining membrane of the ventricle and a layer of nucleus-like particles; it is traversed by several veins. This surface is limited on the outside by the plane of fibres, which, after emerging from it, incline inwards and contribute to form the corpus callosum. On the inside it is limited by the tænia semicircularis, which separates it from the optic thalamus. That portion of the free surface which is seen in the inferior horn of the ventricle has, as already stated, the appearance of a caudiform prolongation of the upper portion; this probably arises from the diminution of the body in thickness at its inferior part, the portion which belongs to the inferior cornu forming the apex of a cone, of which the upper convex portion forms the curvilinear base.

When sections are made through the corpus striatum, it is found to be traversed by very numerous bundles of fibres. It is necessary that these sections should be directed obliquely from below upwards in a direction parallel to the inferior layer of the crus cerebri. The bundles are thicker and more closely approximated to each other inferiorly; but as they ascend, they diverge, and radiate, some forwards, others outwards, and others backwards; some pass nearly vertically upwards. A section made quite in the horizontal direction cuts all these fibres more or less transversely, so that the cut surface presents a grey colour interspersed with white spots of variable size, according as the bundles have been cut transversely or obliquely; but when the section is made in the oblique direction, as above directed, then the surface presents a striated appearance like numerous and regular white veins in a dark marble, the bundles of fibres being cut lengthways.

In tracing the bundles of fibres through the corpus striatum, we find that they divide and subdivide and occasionally anastomose. Each subdivision becomes clothed as it were with grey matter, which fills up the space between it and the adjacent ones. The grey matter ensheathes these bundles of fibres, as the areolar tissue does the fascicles of coarse muscles, and it may be dissected away from them, as we remove the areolar tissue from the muscular bundles.

It is an important problem to determine the exact source of these fibres and their precise destination. There can be no doubt that many of them are continuous with the inferior plane of the crus cerebri. Of those, the major part are usually supposed to pass through to the white substance of the hemisphere, and some no doubt proceed no farther than the corpus striatum. The other fibres which are found in this body may be viewed as taking their point of departure from its vesicular matter, and radiating, some outwards into the centrum ovale, others backwards to the optic thalamus, forming a bond of connection with that body. It must be borne in mind that, as the corpus striatum is a body of considerable thickness, these fibres which emerge from it must proceed in very different planes and with varying degrees of obliquity. Other fibres are found in the corpora striata, which however do not contribute to its striation. These are the fibres of the anterior commissure.

From a comparison of the small amount of fibrous matter in the inferior plane of the crus cerebri with the immense mass which forms the white substance of the hemispheres, (even if we exclude those fibres which form commissures,) it is impossible to suppose that the latter is derived from the former only; nor, indeed, can it be admitted that even the greater part of the fibrous matter of the hemispheres is continuous with that of the crura, whether on their superior or inferior plane. A considerable portion of them doubtless, when traced from the hemispheres downwards, will be found not to pass below the corpora striata or optic thalamus.

We may regard the corpus striatum as a mass of grey matter with fibres implanted in it which connect it with the other parts of the encephalon. These parts are, 1st, the hemispheres; 2d, the optic thalami; 3d, the crura cerebri, mesocephale, and medulla oblongata. Of these last fibres it is probable, (but I am disposed to think far from certain,) that some of those which form the inferior layer of the crus pass through the corpora striata, and diverge among the other fibres of the centrum ovale.

Thus the corpora striata are connected to the optic thalami by fibres which pass from their concave or inner border to those bodies; to the convolutions of the brain by fibres continuous with some of those which form the white substance of the hemisphere, and we have seen that the convolutions of the *insula* have a very close relation to them; to the mesocephale and medulla oblongata by the fibres which form the inferior layer of the crus; and to each other by those which, emerging from them, contribute to form the corpus callosum, and also by the anterior commissure.

The vesicular matter of the corpora striata does not differ from that of the convolutions. It is traversed by a multitude of fibres. These, however, do not form any intricate interlacement as in ganglia, but are collected into bundles of very variable size; the largest being placed at the inferior part of the body, the smallest towards the hemispheres. The free or ventricular portion of the corpus striatum contains comparatively few fibres. When a portion of the striated part of the body is examined under the microscope, the nerve-fibres, of which the bundles are composed, appear to be reduced to their smallest size, and to be very compactly applied to each other, so that they transmit very little light, and therefore put on the appearance of dark cylinders. It is only by very high powers that we can discover their fibrous structure. In many of the bundles the fibres appear to terminate at one extremity as if by forming an adhesion around a large vesicle, faint indications of the nucleus and nucleolus of which may be sometimes seen through the surrounding fibres. The appearance which the fibrous cylinders which exhibit this structure present calls to mind very strongly the representation of the nucleus of a comet with its tail. And this peculiarity of structure may be adduced as an argument that many if not the greater number of the fibres of the striated body form intimate connections with the elements of its vesicular matter.

Optic thalami.—In the internal concave surface of each corpus striatum, the optic thalamus is placed. The latter body is therefore posterior and internal to the former. The lighter colour of the optic thalamus distinguishes it at once from the corpus striatum. The optic thalami come into close relation to each other by their inner surfaces, which form the lateral boundaries of the third ventricle.

Each optic thalamus, like the corpus striatum, presents a free and an attached portion. The former projects into the ventricle—*the intra-ventricular* portion; the latter adheres to the inner side of the corpus striatum and to the mass of the hemisphere, and posteriorly, to the olivary columns, the quadrigeminal tubercles, and the processus cerebelli. The superior surface is free and forms part of the floor of the lateral ventricle; the internal surface is likewise free and forms the lateral wall of the third ventricle, being, however, interrupted in a very small space by the adhesion of the soft commissure. A portion of its external and posterior surface is also free, and projects backwards and outwards into the inferior horn of the lateral ventricle, presenting a pointed extremity in that situation. These free surfaces are smooth and moist, being covered by the membrane of the ventricles. The velum interpositum, which again is overlapped by the fornix, rests upon the superior surface of the optic thalamus.

The optic thalami are placed obliquely, so that they are nearer each other at their anterior than at their posterior extremities. Each measures about an inch and a half in length, nine to ten lines in height, and about eight lines in breadth. In colour they are very much lighter than the striated bodies, and they appear to be covered with a delicate layer of fibrous matter. A band of fibrous matter passes along the inner surface of each from behind forwards, which posteriorly is connected to the pineal gland, and forms, with its fellow, the peduncles of that body.

Beneath the posterior free extremity of the thalamus, situated in the angle between that body and the superior surface of the crus, we find a small rounded eminence of a darkish grey colour perforated by very numerous foramina for the transmission of bloodvessels. This is the *corpus geniculatum internum.* Lower down and more external and anterior, there is another similar body, somewhat smaller and less dark, the *corpus geniculatum externum.* Both of these bodies are connected with the quadrigeminal tubercles. A band of fibrous matter passes from the testes to the external geniculate body, and from the nates to the internal one.

In point of structure the thalamus resembles a ganglion much more closely than does the corpus striatum. A light reddish grey is the colour of the surface when cut into; it has been not inappropriately compared to that of coffee mixed with a good deal of milk (café au lait). When thin sections are examined, they are found to consist of very numerous fibres interlacing freely, with nerve vesicles occupying their intervals. The fibres are not collected into bundles as in the corpus striatum, nor do they take a radiating course in the thalamus. The reticulation which they form is very like that in the ganglia on the posterior spinal roots.

The fibres of the optic thalami, inasmuch as they are very numerous, have extensive connections. Along its ventricular surface they are evidently continuous with those of the hemisphere, which appears to radiate from it to the grey matter of the convolutions. Posteriorly the fibres of the processus cerebelli ad testes and those of the olivary columns pass into it. The anterior pillars of the fornix are connected with it in front, and derive from it some nervous fibres; and below and within, a cylinder of fibres emerge from it to the mamillary bodies. Thus the optic thalami are connected with the hemispheres on one hand, with the olivary columns and with the cerebellum on the other hand. The quadrigeminal tubercles placed upon the processus cerebelli may have some connection with them through the latter bundles of fibres. Although these bodies have been viewed as having a special connection with the optic nerves, it does not appear that those nerves have any relation to them but through the geniculate bodies or the quadrigeminal tubercles. It is important to bear in mind respecting the optic thalami that they are directly continuous with the superior portion of the crus cerebri, so that in viewing a vertical section of the encephalon we see no line of demarcation between. The thalamus grows, as it were, from the superior extremity of the crus; it is recognised from the latter by its swelling into an ovoidal mass. It is emphatically, as Willis long ago expressed it, an *epiphysis* upon the crus cerebri; and in this sense it may be classed with the striated bodies and the quadrigeminal tubercles, which, with the thalami, form a series of gangliform masses, disposed in pairs, one beyond the other.

The geniculate bodies, although intimately connected with the optic thalami, appear to be distinct from them, but very similar in structure. A section made into the thalamus through either of them shows a distinct line of demarcation between them. The optic tracts adhere to the lower surface of each thalamus by their inner margins, and when followed backwards are found to form a very evident connection with both the geniculate bodies.

Corpora mamillaria.—These bodies may be conveniently noticed here, as forming part of the series of gangliform masses in connection with the brain. They are of a spherical shape, covered on the exterior by very pure white matter, which is apparently derived from the anterior pillars of the fornix. When cut into, they are found to consist of a mixture of vesicular and fibrous matter, surrounded by a thin cortex of the latter. Microscopic examination proves this structure of the interior substance to be of the same nature as that of ganglia, and to resemble the optic thalamus.

The fibrous matter is connected, at the upper part of each body with the anterior pillar of the fornix, and on the outside with a fasciculus of fibres from the optic thalamus. It has been supposed that these two bundles are continuous, and that the mamillary body results from a twisting of the anterior pillar of the fornix as it changes its direction to pass into the substance of the thalamus. But the ganglionic structure of the mamillary bodies is unfavourable to this view, and renders it more probable that they are independent structures, exercising proper functions as nervous centres; and the constancy of these bodies in, at least, the mammiferous series, increases this probability.

Of the commissures of the brain.—A large number of fibres connected with the hemispheres or the two gangliform bodies just described, seem to serve the purpose of connecting different parts, either on the same side of the mesial plane, or on opposite sides of it. Those on the same side constitute the longitudinal commissures; those on opposite sides the transverse.

Of the longitudinal commissures.—These are four in number. They all evidently belong to the same system of fibres, separated from each other by the developement of intermediate parts. That which is on the highest plane is the *superior longitudinal commissure*, which is the fibrous matter of the internal convolution. Internal and a little inferior to this is a second, very small, band of fibres, *longitudinal tract*, (Vicq. d'Azyr,) which passes from before backwards along the middle of the corpus callosum, parallel to the superior longitudinal commissure, from which it is separated only by the grey matter of the convolution. Both these commissures are separated by the corpus callosum from a third, which takes a parallel course to them, namely, the *fornix*, which occupies a plane considerably inferior to both. External to this and separated from it by the ventricular projection of the optic thalamus, we find a fourth band, which passes parallel to the fornix: this is the *tænia semicircularis*.

As these parts have been already described, it will be unnecessary to do much more at present than indicate the connections which they serve to maintain.

1. *The superior longitudinal commissure* connects the convolutions of the inferior surface of the anterior lobe with the hippocampus major; and as its fibres pass above the corpus callosum they form connections with some of the other convolutions on the internal surface of the hemisphere (*fig.* 395).

2. *The longitudinal tracts* of the corpus callosum may be traced from about the same region of the inferior surface of the anterior lobe as the preceding commissure, near the perforated space, and they pass backwards, winding over the posterior reflection of the corpus callosum to its inferior surface.

3. The *fornix** is, next to the corpus callosum, the most extensive of the cerebral commissures. That it consists of longitudinal fibres cannot be doubted. Although commonly described as a single structure united at the body of the fornix, and spreading backwards and forwards by its crura, it nevertheless is distinctly divisible along the middle line into two perfectly symmetrical portions. The adhesion of the transverse fibres of the corpus callosum on its upper surface, and of the terminal fibres of its posterior reflection on its inferior surface which form *the lyra*, is the principal bond of union of these two lateral halves of the fornix.

The separation of its anterior pillars in front affords strong indication of its double form. These pillars pass downwards in a curved course, through the grey matter of the tuber cinereum, to the mamillary bodies, which are connected to the optic thalami by a bundle of fibres which may be easily traced into them. This bundle is described by Reil as the *root* of the anterior pillar of the fornix. From the gangliform structure of the corpus mamillare, I prefer to regard this band as a medium of connection with the optic thalamus, and to trace the anterior pillars to the mamillary body.

The parts with which the fornix is connected in front are the optic thalami, the mamillary bodies, and the septum lucidum, which consists of fibres having the same physiological import as those of the corpus callosum, altered however in direction by the backward position of the anterior pillars, which adhere to the body of the fornix. The tuber cinereum and the grey matter which adheres to the lower half of the inner surface of each optic thalamus, are connected with it;

* This commissure is called *voûte à trois piliers* by the French, *Trigone cérébrale*, Chaussier: Ψαλις, σωμα Ψαλιοειδες of the Greeks. Mr. Solly has given an excellent delineation of the fornix in his work on the brain, pl. ix.

and as its anterior pillars pass upwards in this situation, they receive fibres from the neighbouring convolutions. These pillars remain separate from the mamillary bodies to the foramen of Monro, where they adhere to each other and form the apex of the body of the fornix. Traced backwards, the fibres of the fornix pass into the posterior and inferior horns of the lateral ventricle. In the former they connect themselves with the hippocampus minor by expanding over it, and in the latter they spread over the hippocampus major, forming the posterior pillar of the fornix, or tænia hippocampi.

The relation of the anterior pillars of the fornix to the foramen commune anterius has been already sufficiently described. Superiorly the fornix adheres to the corpus callosum or to the septum lucidum, and the anterior commissure crosses in front of its anterior pillars, and almost touches them.

4. The fourth longitudinal commissure is the *tænia semicircularis*. It may be traced from the corpus mamillare outwards and backwards in the groove between the optic thalamus and corpus striatum into the inferior horn of the lateral ventricle, when its fibres mingle with those of the middle lobe. It is evidently part of the same system of fibres with the fornix.

Take away the corpus callosum, the grey matter of the internal convolution, the ventricular prominence of the optic thalamus, and all these commissures fall together and become united as one and the same series of longitudinal fibres.

It is very remarkable how few fibres pass between the great mass of the cerebrum and the cerebellum. The *processus cerebelli ad testes* are the only fibres which can be regarded as forming commissures between these two segments of the encephalon, and they are of the nature of longitudinal commissures.

The *transverse commissures* are the *corpus callosum*, the *anterior commissure*, the *posterior commissure*, the *soft commissure*.

1. The *corpus callosum*, so called according to some from the density of its tissue, is the great commissure of the lateral halves of the brain proper—*commissura cerebri maxima* of Soemmering. The fasciculated character of this structure is as obvious as that of any nerve in the body, and the direction of the fibres is clearly from one hemisphere to the other.

From the description already given of the corpus callosum, it is evident that its fibres sink into the white substance of each hemisphere above the level of the corpora striata, as well as into that of the anterior and of the posterior lobes. By its principal or horizontal portion it connects the white matter of the lesser centrum ovale of each side, and by the fibres which form the anterior and posterior reflexions it connects the anterior and posterior lobes. It needs only a very superficial dissection to ascertain thus much.

To determine the precise fibres with which those of the corpus callosum are continuous, and the relation which they bear to the lateral ventricles, demands a much more minute dissection. This must be done, according to the directions of Foville, who has given a most elaborate description of this commissure, by carefully separating it in the transverse direction from the internal convolution, on a hardened brain. Pursuing the dissection in this direction, it may be detached from the substance of the hemispheres as far outwards as the external border of the corpus callosum and optic thalamus. Along this edge the fibres curve downwards and inwards, and appear to become continuous with some of those which radiate from those bodies. The anterior and posterior fibres enclose the anterior and posterior horns of the lateral ventricles in radiating forwards and backwards from the corpora striata and optic thalami to those parts of these cavities.

This view of the connections of the corpus callosum would indicate it to be a commissure between the thalami and corpora striata, or between the crura cerebri, as Tiedemann supposed, rather than between the hemispheres. Nothing is more difficult than the dissection of the fibres of the corpus callosum beyond the internal convolution: and it cannot be regarded as in any degree certain that the connections of its fibres are limited to those above described.

The developement of the corpus callosum in the fœtus, prior to that of the hemispheres or convolutions, is favourable to the view of its connections maintained by Tiedemann and Foville. Comparative anatomy is, however, more in accordance with the opinions of Gall and Reil, that it is a commissure between the convolutions of opposite sides. It exists only in those animals in which convolutions are amply developed. In Fish, Reptiles, and Birds it is absent, and the Mammalia with least perfect brains, as the Rodents and Marsupialia.

The corpus callosum is a stratum of considerable thickness. Its fibres are situate on different planes, which interlace with each other so much as to render it impossible to separate any layer for any distance, and the difficulty is much increased as the fibres are nearer the white mass of the hemispheres.

2. *The anterior commissure* may be regarded as truly a bond of connection between the hemispheres, as well as between the corpora striata. It is a cylindrical cord of fibrous matter, very definite in its course and connections, and easily traced throughout its entire extent. Its situation in front of the anterior pillars of the fornix has been already described. If followed on either side from this central portion, it may be traced through the grey matter of the anterior and inferior portion of each corpus striatum into the fibrous matter of each middle lobe of the brain. Its course is curved with convexity directed forwards. As it passes outwards on each side it becomes flattened, and after it has traversed each corpus striatum, it expands considerably and its fibres

radiate extensively. It may be stated to connect the convolutions of the middle lobes and the corpora striata.

3. *The posterior commissure* is a band of fibres, extended between the posterior extremities of the optic thalami, upon which rests the base of the pineal body. Those fibres, which immediately support that body, have been distinguished as the *pineal commissure;* but as they are evidently part of the same system as those which constitute the posterior commissure, there seems no good reason for separating them.

4. *The soft commissure* is also extended between the thalami. It is composed of vesicular matter with fibres, which pass from one side to the other. The intermixture of its fibres with vesicular matter distinguishes it from the other transverse commissures already described. A layer of a similar nature connects the locus niger of each crus cerebri, and fills up the space between the crura—*interpeduncular space.* This has been already described as the *pons Tarini, posterior perforated space.* It consists of fibrous matter intermixed with vesicular, extended between the crura cerebri. It seems analogous to the soft commissure, and therefore entitled to be regarded as a commissure.

Of the manner in which the commissures connect the various parts between which they are placed, it is difficult to form an exact opinion. It is most probable that they form an intimate union with the grey matter of the segments which they serve to connect. It might also be conjectured that they are continuous with some of the fibres of the segments which they unite, or that they interlace with them in some intricate way, so as to come into intimate or frequent contact with them.

Tuber cinereum.—At the base of the brain we have already described a layer of pale grey matter which fills up the interval between the mamillary bodies and the optic commissure. It extends above the optic commissure forwards to the anterior reflexion of the corpus callosum, and forms intimate connections with the anterior pillars of the fornix, the optic tracts, the septum lucidum, and at the floor of the third ventricle with the optic thalami. It consists of vesicular matter with fibres, and resembles very much the soft commissure, to which it is very probably analogous in office.

The process called *infundibulum* or *pituitary process* extends from the inferior surface of the tuber cinereum down to the pituitary body. It is hollow, wide above, where it communicates with the third ventricle, and narrow below at the pituitary body. When cut across, fluid will escape from the third ventricle through it, and a probe passes readily from that cavity into it. It is composed of a layer of granules, derived, no doubt, from the epithelial lining of the third ventricle, and some vesicular matter with bloodvessels and fibrous tissue, which latter is derived from the pia mater, and the special sheath of arachnoid reflected upon it.

Pituitary body.—The process just described is the connecting link between the brain and that glandiform body, *the pituitary gland* or *hypophysis.* This body, situate in the sella Turcica, is of a rounded form, longer in the transverse than the antero-posterior direction, concave on its superior surface, into which the pituitary process is inserted. It is surrounded by dura mater, which projects over it, leaving an opening for the passage of the infundibulum.

The pituitary body is about six lines in its transverse diameter and three lines from before backwards: its weight, including the infundibulum, is about eight grains. It consists of two lobes, one anterior, the other posterior. The former is kidney-shaped and lodges the latter in the notch of its posterior edge. In point of size the anterior lobe is nearly double the posterior.

The colour of the posterior lobe is lighter than that of the anterior, and resembles that of the grey matter of the brain.

This body is proportionally larger in early life than at the later periods, and it is certainly more developed in the lower mammalia than in man. It is very large in fishes, and probably reaches its maximum of size in that class of animals.

The structure of the pituitary body resembles very much the grey cerebral matter. It is composed of large nucleated vesicles, surrounded by a granular matrix, with bundles of white fibrous tissue. This fibrous tissue either forms an essential element in its constitution, or accompanies the bloodvessels which are found in it in great numbers. Its substance is soft, but not so soft as the cerebral matter, and when pressed between the fingers is reduced to a greyish pulp, like the substance of an absorbent gland in an early stage of suppuration.

Earthy concretions have been occasionally but very rarely found in the pituitary body. This circumstance, its colour, its glandiform character, and its extra-cerebral situation in connexion with the third ventricle, give it a certain degree of analogy to the pineal body. But in this latter nervous fibres have been found, of which I have failed to discover any trace in the pituitary, nor is the pituitary body connected to the brain by fasciculi of fibres as the pineal body is. The use of both is equally involved in obscurity; but from their constancy it may be argued that their function is not unimportant. It has been supposed that the pituitary body is a large ganglion belonging to the sympathetic system: this opinion, however, wants the all-important foundation of anatomy to rest upon, inasmuch as we find that the body in question is devoid of the anatomical characters of a ganglion. It may with more propriety be classed with the glands without efferent ducts; and from its numerous vessels, and its close relation to part of the venous system within the cranium, it may be connected with the process of absorption or removal of the effete particles of the brain.

Of the ventricles of the brain.—The third ventricle results from the apposition of the lateral halves of the brain along the median plane, and the lateral ones from the folding inwards, above and below, of the convoluted surface of each hemisphere. They must not therefore be regarded as cavities hollowed in the substance of the brain: on the contrary, their walls must be viewed as part of the cerebral surface, and the eminences which project from them as convolutions. The corpora striata and optic thalami are from their structure entitled to be considered in this light, and still more the hippocampi, which, however, are somewhat complicated by the addition of the layers of white matter derived from the fornix.

The distinction between the lateral and the middle or third ventricle results from the developement of the corpus callosum and of the fornix, which form horizontal strata by which the ventricles are closed in above; and the extension of the anterior pillars of the fornix downwards, and the close application of the free margin of the body of the fornix to the optic thalami, assign more complete limits to the third ventricle.

The fourth ventricle is also evidently formed by the lateral adaptation of the symmetrical halves of the medulla oblongata. The iter is obviously a continuation of it closed behind by the quadrigeminal bodies and their connecting fibres. This ventricle remains open in the embryo, uncovered by any portion of the encephalon until the full developement of the cerebellum causes it to extend over it.

The fifth ventricle must be viewed as originally part of the third, which has been closed off by the full developement of the septum lucidum and fornix, and the union of their lateral halves along the median plane.

All these cavities are lined by a delicate membrane nearly allied to, if not identical with, serous membranes. It is covered by an epithelium, ciliated according to Purkinje and Valentin, beneath which are delicate fibres of areolar tissue exactly of the same kind as those found in connection with serous membranes. I have never seen any basement membrane. This membrane is reflected around the processes of pia mater which are found in the ventricles, and in this respect presents an additional point of analogy to the serous membranes, the portion which lines the walls of the ventricles corresponding to the parietal layer, and that which adheres to the pia mater resembling the visceral layer of those membranes. It is the reflection of this membrane from the walls to the enclosed pia mater which serves to shut off the ventricular cavity from the sub-arachnoid space, at the anterior part of the horizontal fissure, and at the inferior extremity of the fourth ventricle. If any communication take place between the intra-ventricular and sub-arachnoid fluid, it must be, as already remarked, by transudation through this membrane.

Of the circulation in the brain.—Haller calculates that the human brain receives rather more than one-fifth of the whole blood of the body. Whether this calculation be correct or no, it is certain that an organ of such great size, of such high vital endowments, so active, and which exerts so considerable an influence upon all other parts of the body, must necessarily require a large supply of the vital fluid. Four large arteries carry blood to the brain, namely, the two *internal carotids* and the two *vertebrals*. Each carotid penetrates the cranium at the foramen on the side of the sella Turcica, and almost immediately divides into three branches, the *anterior* and the *middle cerebral* arteries and the *posterior communicating* artery.

The *anterior cerebral arteries* supply the inner sides of the anterior lobes of the brain: they ascend through the great longitudinal fissure, and pass along the upper surface of the corpus callosum, giving off branches to the inner convolutions of both hemispheres of the brain. These arteries anastomose with each other just beneath the anterior margin of the corpus callosum by a transverse branch, called *anterior communicating artery*. The *middle cerebral arteries*, the largest branches of the carotid, pass outwards in the fissures of Sylvius, and supply the outer convolutions of the anterior lobes, and the principal portion of the middle lobes. At the inner extremity of each fissure of Sylvius numerous small branches of these arteries penetrate, to be distributed to the corpus striatum. The choroid arteries which supply the choroid plexus sometimes arise from these arteries, but also occasionally come from the carotid itself. The *posterior communicating artery* is an anastomotic vessel, which passes backwards along the inner margin of the middle lobe on the base of the brain, and communicates with the posterior cerebral artery, a branch of the basilar.

The *vertebral* arteries, having passed through the canals in the transverse processes of the cervical vertebræ, enter the cranium through the occipital foramen towards its anterior part. In their ascent they incline towards each other in front of the medulla oblongata, and at the posterior margin of the pons they coalesce to form a single vessel, the *basilar*, which extends the whole length of the pons.

The *vertebral* arteries furnish the *anterior* and *posterior spinal* arteries, and the *inferior cerebellar* arteries. These last vessels arise from the vertebrals very near their coalescence; they pass round the medulla oblongata to reach the inferior surface of the cerebellum, to which they are principally distributed.

From the basilar artery numerous small vessels penetrate the pons. At its anterior extremity it divides into four arteries, two on each side. These are, the two *superior cerebellar*, and the two *posterior cerebral* arteries.

The superior cerebellar arteries pass backwards round the crus cerebri, parallel to the fourth nerve, and divide into numerous branches on the upper surface of the cerebellum, some of which anastomose with branches of the inferior cerebellar artery over the posterior margin of the cerebellum. Some branches of these arteries are distributed to the velum interpositum.

The posterior cerebral arteries are the largest branches of the basilar. They diverge and pass upwards and backwards round the crus cerebri, and reach the inferior surface of the posterior lobe, anastomosing in the median fissure with ramifications of the anterior cerebral, and on the outside with branches of the middle cerebral arteries. Numerous small vessels pass from these arteries at their origin, and penetrate the interpeduncular space, and one or two are distributed to the velum. Shortly after its origin each of these arteries receives the posterior communicating branch from the carotid.

A remarkable freedom of anastomosis exists between the arteries of the brain. This takes place not only between the smaller ramifications, but likewise between the primary trunks. The former is evident all over the surface of the cerebrum and cerebellum. The latter constitutes the well-known *circle of Willis*. This anastomosis encloses a space, somewhat of an oval figure, within which are found the optic nerves, the tuber cinereum, the infundibulum, the corpora mamillaria, and the interpeduncular space. The anterior communicating artery, between the anterior cerebral arteries, completes the circle in front. The lateral portion of the circle is formed by the posterior communicating artery, and it is completed behind by the bifurcation of the basilar into the two posterior cerebral arteries. Thus, a stoppage in either carotid, or in either vertebral, would speedily be remedied. The coalescence of the vertebrals to form the basilar affords considerable security to the brain against an impediment in one vertebral; and, should the basilar be the seat of obstacle, the anastomoses of the inferior cerebellar arteries with the superior ones would ensure a sufficient supply of blood to that organ. If either or both carotids be stopped up, the posterior communicating arteries will supply a considerable quantity of blood to the intracranial portions of them; or, if one carotid be interrupted, the anterior communicating branch will be called into requisition to supply blood from the opposite side.

Interruption to the circulation in both carotids and both vertebrals is productive of a complete cessation of cerebral action, and death immediately ensues, unless the circulation can be quickly restored. This was proved clearly by Sir A. Cooper's experiments on rabbits. The circulation may, however, be interrupted in both carotids, or in both vertebrals, without permanent bad effect; or in one carotid or one vertebral, provided the condition of the remaining vessels be such as not to impede the circulation in them. In cases where the neighbouring anastomotic branches are not sufficient to restore the circulation to a part from which it has been cut off by the obliteration of its proper vessel, the cerebral substance of that region is apt to experience a peculiar form of softening* or wasting, which is distinguished by the absence of any discoloration by the effusion of blood, or of any new matter.

The four great channels of sanguineous supply to the brain are continued up straight from the aorta itself, or from an early stage of the subclavian. The columns of blood contained in them are propelled very directly towards the base of the brain, through wide canals. Were such columns to strike directly upon the base of the brain, there can be no doubt it would suffer materially. Considerable protection, however, is afforded to the brain; first, by the blood ascending against gravity, during at least a great portion of life; secondly, by a tortuous arrangement of both carotids and vertebrals before they enter the cranial cavity; the carotid being curved like the letter S in and above the carotid canal, and the vertebral being slightly bent between the atlas and axis, then taking a horizontal sweep above the atlas, and after it has pierced the occipito-atlantal ligament, inclining obliquely upwards and inwards; thirdly, by the breaking up of the carotids into three branches; by the inclined position of the vertebrals, and by their junction into a single vessel, which takes a course obliquely upwards, and afterwards subdivides into smaller branches. Such arrangements most effectually break the force of the two columns, and, as it were, scatter it in different directions.

A further conservative provision is found in the manner in which the bloodvessels penetrate the brain. The larger arterial branches run in sulci between convolutions, or at the base of the brain; smaller branches come off from them, and ramify on the pia mater, breaking up into extremely fine terminal arteries, which penetrate the brain; or these latter vessels spring directly from the larger branches, and enter the cerebral substance. As a general rule, no vessel penetrates the cortical layer of the brain, which, in point of size, is more than two removes from the capillaries; and, whenever any vessel of greater size does pierce the cerebral substance, it is at a place where the fibrous matter is external, and that part is perforated by foramina for the transmission of the vessels. Such places are the locus perforatus, the interpeduncular space, &c. The capillaries of the cerebral substance are easily seen to possess an independent diaphanous wall, with cell-nuclei disposed at intervals. The smaller arteries and veins can also be admirably studied in the pia mater of the brain.

The venous blood is collected into small veins, which are formed in the pia mater at various parts of the surface, and in the interior of the brain. The superficial veins open by short trunks into veins of the dura mater, or into the neighbouring sinuses; the superior longitudinal, the lateral, and the straight sinuses receiving the greatest number. Those from the interior form two trunks, *venæ magnæ Galeni*, which pass out from the ventricles between the layers of the velum interpositum. The cerebral veins are devoid of valves.

We remark here, that the venous blood of the brain is returned to the centre of the circu-

* In the last volume of the Med. Chir. Trans. I have related a remarkable case in which white softening of one hemisphere followed the plugging of the common carotid on the same side by coagulum.

lation through the same channel as that of the dura mater, of the cranial bones, and of the eyeball: the internal jugular veins are the channel towards which the venous blood of the cranium tends. An obstacle, therefore, in both or either of these vessels must affect the entire venous system of the brain, or at least that of the corresponding hemisphere. A ligature tied tightly round the neck impedes the circulation, and may cause congestion of the brain. The bodies of criminals who have died by hanging exhibit great venous congestion, both of the walls and the contents of the cranium, in consequence of the strong compression to which the veins have been submitted.

We have seen that, when the blood of one carotid artery is cut off, the parts usually supplied by it are apt to become exsangueous and softened; and this is more especially the case if the vertebral be stopped up, or the circulation in it impeded. And it has been remarked, that these effects will follow the application of a ligature to either common carotid artery.

Notwithstanding these facts, a doctrine has received very general assent, and the support of men of high reputation, which affirms that the absolute quantity of blood in the brain cannot vary, because that organ is incompressible, and is enclosed in a spheroidal case of bone, by which it is completely exempted from the pressure of the atmosphere.

The cranium, however, although spheroidal, is not a perfectly solid case, but is perforated by very numerous foramina, both external and internal, by which large venous canals in the diploe of the bones communicate with the circulation of the integuments of the head as well as with that of the brain; so that the one cannot be materially affected without the other suffering likewise. And as the circulation in the integuments is not removed from atmospheric pressure, neither can that which is so closely connected and continuous with it, be said to be free from the same influence. Still it must be admitted, that the deep position of the central vessels, and the complicated series of channels through which they communicate with the superficial ones, protect them in some degree from the pressure of the air, and render them less amenable to its influence than the vascular system of the surface.

If it were essential to the integrity of the brain that the fluid in its bloodvessels should be protected from atmospheric pressure (as the advocates of this doctrine would have us to believe), a breach in the cranial wall would necessarily lead to the most injurious consequences; yet, how frequently has the surgeon removed a large piece of the cranium by the trephine without any untoward result! Some years ago I watched for several weeks a case in which nearly the whole of the upper part of the cranium had been removed by a process of necrosis, exposing a very large surface to the immediate pressure of the atmosphere; yet in this case no disturbance of the cerebral circulation existed. In the large and open fontanelles of infants we have a state analogous to that which art or disease produces in the adult: yet the vast majority of infants are free from cerebral disease for the whole period during which their crania remain incomplete; and in infinitely the greatest number of cases in which children suffer from cerebral disease, the primary source of irritation is in some distant organ, and not in the brain itself.

It cannot be said that the brain is incompressible. That only is incompressible, the particles of which will not admit of being more closely packed together under the influence of pressure. That the brain is not a substance of this kind is proved by the fact that, while it is always undergoing a certain degree of pressure as essential to the integrity of its functions, a slight increase of that pressure is sufficient to produce such an amount of physical change in it as at once to interfere wlth its healthy action. Too much blood distributed among its elements, and too much serum effused upon its surface, are equally capable of producing such an effect.

Majendie's experiments, described in a former part of this article, show that the brain and spinal cord are surrounded by fluid, the pressure of which must antagonise that which is exerted through the bloodvessels. The removal of this fluid disturbs the functions of these centres, apparently by allowing the vessels to become too full. The pressure exerted by the former may be called the fluid pressure from without the brain; that by the blood, the pressure from within. As long as these two are balanced, the brain enjoys a healthy state of function, supposing its texture to be normal. If either prevail, more or less of disturbance will ensue. Their relative quantities, if not in just proportion, will bear an inverse ratio to each other. If there be much blood, the surrounding fluid will be totally, or in a great measure, deficient; if the brain be anæmic, the quantity of surrounding fluid will be large.

The existence of these two antagonizing forces may be taken as a proof that either of them may prevail; and, therefore, from the presence of the cerebro-spinal fluid, we may infer that the actual quantity of circulating blood in the brain is liable to variation.

The cerebro-spinal fluid is a valuable regulator of vascular fullness within the cranium, and a protector of the brain against too much pressure from within. So long as it exists in normal quantity it resists the entrance of more than a certain proportion of blood into the vessels. Under the influence of an unusual force of the heart an undue quantity of blood may be forced into the brain, the effects of which will be, first, the displacement of a part or of the whole surrounding fluid; and, secondly, the compression of the brain.

When the brain receives too little blood, the requisite degree of pressure will be maintained, and the healthy cerebral action preserved, if the surrounding fluid do not increase too rapidly. But if the brain be deprived of its due proportion of blood by some sudden depression of the heart's power, there is neither time nor source for the pouring out of a new fluid, and a state of syncope or of delirium will ensue. Such seems to be the explanation of those cases of delirium which succeed to hæmorrhages, large bleedings, or the sudden lighting up of inflammation in the pericardium or within the heart. In nearly all these cases, however, it is important to notice that the blood is more or less damaged in quality, deficient in some of its staminal principles, or charged with some morbid matter; and this vitiated state of the vital fluid has no doubt a considerable share in the production of the morbid phenomena.*

Of the encephalic nerves.—There are no common characters possessed by these nerves, such as have been enumerated at a preceding page for the spinal nerves. They are, however, disposed in pairs, and are quite symmetrical. With the exception of the olfactory, optic, and third pair, they are all connected with the mesocephale or medulla oblongata.

The arrangement of these nerves originally proposed by Willis has been so long adopted in this country and on the continent that no advantage would arise from abandoning it, unless some other of an unexceptionable nature could be substituted for it. It has, therefore, been followed in this work, and the anatomy and physiology of the encephalic nerves have been described in articles prefixed by their numerical titles, in all cases except the olfactory and optic, and the eighth pair of nerves.†

Twelve pairs of nerves are found in connection with the base of the encephalon. Five pairs have been so classed by Willis as to form two in his arrangement, three pairs being allotted to his eighth pair of nerves, and two to his seventh. Willis's arrangement, therefore, comprises nine pairs of nerves, which he enumerates, beginning at the anterior and passing to the posterior part of the base of the brain. These are the first pair or *olfactory* nerves; the second pair or *optic;* the third pair, *motores oculorum;* the fourth pair, *pathetici;* the fifth pair; the sixth pair, *abducentes oculi;* the seventh pair, including the *portio mollis* or *auditory* nerve, and the *portio dura* or *facial* nerve; the eighth pair, including the *glosso-pharyngeal*, the *pneumo-gastric*, and the *spinal accessory;* the ninth pair or *hypoglossal.* The first cervical nerve or the *sub-occipital* was considered by Willis as an encephalic nerve and counted as the *tenth pair.*

As the cranium may be shewn to be composed of the elements of three vertebræ, it has been attempted to prove that among these nerves some may be classed with the vertebral or spinal nerves. The fifth is obviously of this kind from its anatomical characters, namely, two roots; one, small, ganglionless; the other large, ganglionic; but with the former, which is analogous to the anterior root of a spinal nerve, the third, fourth, and sixth nerves may be conjoined from their similarity in structure and distribution. Thus one *cranio-vertebral* nerve is formed, the anterior root of which consists of the small portion of the fifth, the third, fourth, and sixth nerves; and the posterior or sensitive root, of the large portion of the fifth. A second cranio-vertebral nerve consists of the eighth pair, to which might be added the facial contributing to its motor portion; and a third is formed by the hypoglossal. The analogy, especially in the latter case, is far from being very obvious.

Sketch of the microscopical anatomy of the spinal cord and brain.—We conclude our account of the anatomy of the spinal cord and brain with a rapid glance at the present state of our knowledge of their minute anatomy as revealed by microscopical observation.

The elements of the two kinds of nervous matter, *fibrous* and *vesicular*, have been already sufficiently described. We shall only remark here that the great object of the anatomist's research should be to find out the precise manner in which the nerve-fibres are united with the nerve-vesicles. Of their intimate connection there can be no doubt,—much less of the influence which they are capable of exerting mutually upon each other.*

Among the peculiarities of the fibrous matter in the centres it may be here stated that the fibres pass through a much greater range of size than in the nerves; that here we meet with nerve-tubes of the largest size, and, on the other hand, with minute fibres which seem to be continuous with the branching processes of the caudate nerve-vesicles. These fibres are perfectly transparent and differ from the nerve-tubes in the absence of any of the white substance of Schwann, and of the tubular membrane.

Some idea of the relation of the vesicular and fibrous matter in different parts of the cerebro-spinal centre may be formed by examining thin sections of the several portions of them made in various directions. It is impossible to make these sections sufficiently thin to enable us to explore a large surface with a high power, for which great transparency is necessary. Such sections, however, may be examined with low powers, as Stilling and Wallach have done. It is important, however, to notice that the appearances observed in this way afford no *certain* indication of the course and direction of the nerve-fibres, nor of the situation of the finer elements of the vesicular matter. The nerve-tubes are too minute to admit of being followed with an object-glass which magnifies less than from two hundred to three hundred diameters; yet Stilling's researches have been made with a power of no more than ten or twelve diameters.

The fibrous matter of the spinal cord consists of some fibres which pass either in a vertical direction, or obliquely, taking a long course, and deviating but slightly from the parallel to the axis of the cord. The fibres of the posterior columns are the most obviously longitudinal, and those which lie quite on the surface of the antero-lateral columns follow very much the same direction. Among the elements of the grey matter, fibres are found in great numbers,

* The subject of the circulation in the cranium has been very ably discussed by Dr. G. Burrows in the Lumleian Lectures for 1843, Lond. Med. Gazette, vol. xxxii.

† The olfactory nerve is described in the atricle Nose, the optic in Optic Nerves, and the eighth pair under the titles of its three portions.

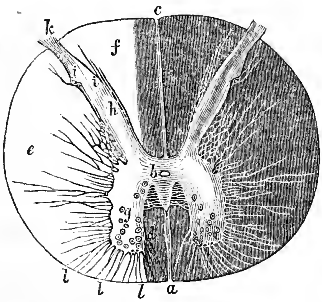
* See the article Nerve, and pp. 646, 7, et seqq.

the direction of which is probably oblique or transverse, as considerable portions of them may be seen taking such a direction when a piece of grey matter, cut transversely, is examined under the microscope.

The grey matter of the cord contains caudate and spherical vesicles imbedded in their usual granular matrix. They are found in the horns as well as in the commissure. The caudate vesicles are most numerous, and distend in the anterior horn and at the root of the posterior one. The remainder of the posterior horn and the gelatinous substance which is found at its posterior border, resemble very closely in structure the grey matter of the cerebral convolutions.

By examining thin transverse sections of the cord, carefully hardened by immersion in spirits, a good view of the relative disposition of the grey and fibrous substances may be obtained. Stilling has carried investigations of this kind to a great extent, and has published some beautiful plates, which are quite true to nature. *Fig.* 396 is copied from one of them.

Fig. 396.



Transverse section of human spinal cord, close to the third and fourth cervical nerves. Magnified ten diameters. (*From Stilling.*)

f, posterior columns; *i i*, gelatinous substance of the posterior horn; *k*, posterior root; *l*, supposed anterior roots; *a*, anterior fissure; *c*, posterior fissure; *b*, grey commissure, in which a canal is contained, which, according to these writers, extends through the length of the cord; *g*, anterior horn of grey matter containing vesicles; *e*, antero-lateral column, from *k* to *a*.

It is impossible, however, to obtain any information from such examinations, except of the most general kind. On referring to the figure, the reader will perceive several lines, of the same colour and appearance as the central mass, to radiate from each horn of the grey matter to the surface of the cord, and not only to its external surface, but to that of its fissures. At whatever part of the cord the section be made, whether on a level with the roots of the nerves or between their points of emergence, the same appearance of radiating lines is seen, and the radiation will be found to extend between the central grey matter and whatever part of the surface of the cord the pia mater comes into contact with.

Stilling and Wallach suppose that these lines are continuous with the roots of the nerves; that they are, in fact, nerve-tubes proceeding from the grey matter to form these roots. But this supposition seems quite untenable, for the following reasons: 1st, because these lines are met with in situations intermediate to the points of emergence of the nerves; 2dly, because they pass to situations, such as the surface of the fissures, from which no nerve-roots emanate; 3dly, because, if they were nerve-tubes, they could not be so distinctly seen with so low a power. It is much more probable that they may be processes of grey matter prolonged towards the surface, to which bloodvessels may pass from the pia mater, or simply bloodvessels passing from the pia mater to the grey matter. In some well-injected specimens, which Mr. Smee had the goodness to shew me lately, the bloodvessels were seen to take exactly the same direction and course as these lines.

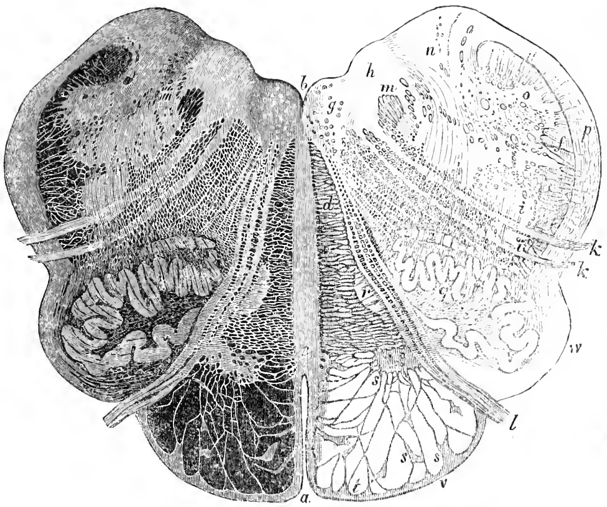
Besides the nerve-tubes which are found in considerable numbers in the grey matter, the branching processes of the caudate vesicles are met with in it also, which may be distinguished from the nerve-tubes by the absence of the white substance of Schwann, by their greyish colour, by their branching, and by their minutely granular texture. Capillary bloodvessels are met with in great numbers, ramifying in the grey matter, where they are much more numerous than in the fibrous matter.

Stilling and Wallach describe a canal passing through the centre of the grey commissure, and extending the whole length of the cord. This is certainly visible in most regions, but not in all. It seems to me to have much more the appearance of a bloodvessel than of a canal. According to these authors, it is the persistent condition of the much-talked of canal of the spinal cord referred to at a previous page. Its situation in the grey matter seems rather opposed to this view. The point, however, is one upon which I am not prepared to express a decided opinion at present, and which deserves more extended careful examination.

From a review of the preceding statements, it is plain that a large number of fibres pass into the grey matter of the cord, and probably form some intimate connection with its minute elements; and this fact is favourable to the supposition that the spinal nerves derive their origin, at least partly, from the grey matter. It must be admitted, either that these fibres unite with the vesicles of the grey matter in some way, or that they pass up to the brain through the grey matter; the former seems the more reasonable supposition, and more consistent with the apparent oblique or transverse direction which the fibres take in the grey matter.

The minute structure of the medulla oblongata resembles in many particulars that of the spinal cord. There is not, however, so complete an isolation of the fibrous matter in it as in the latter. Excepting in the anterior pyramids, and quite on the posterior and lateral surfaces, the two kinds of nervous substance freely intermingle. The anterior and posterior pyramids and the restiform bodies consist, at least in great part, of longitudinal fibres, but the remainder of the fibrous matter appears to be made up of transverse or oblique fibres. Most of these are doubtless connected with the roots of the many nerves which arise from the medulla oblongata. Stilling refers to special accumulations of vesicular matter connected with the roots of each nerve, and which probably form its proper origin. These contain large vesicles. It is impossible to give an exact interpretation to all the parts which are seen by his method of examination, imperfectly defined as they are from the use of such low magnifying powers. It would be waste of time and space to do more than refer to the representation given by Stilling (*fig.* 397) of the

Fig. 397.



Transverse section of the medulla oblongata through the lower third of the olivary bodies. (From Stilling.) Magnified ten diameters.

a, anterior fissure; *b*, fissure of the calamus scriptorius; *c*, raphé; *d*, anterior columns; *e*, lateral columns; *f*, posterior columns; *g*, nucleus of the hypoglossal nerve, containing large vesicles; *h*, nucleus of the vagus nerve; *i*, *i*, gelatinous substance; *k*, *k*, roots of the vagus nerve; *l*, roots of the hypoglossal, or ninth nerve; *m*, a thick bundle of white longitudinal fibres connected with the root of the vagus; *n*, soft column (*Zartstrang*, Stilling); *o*, wedge-like column (*Keelstrang*, Stilling); *p*, transverse and arciform fibres; *q*, nucleus of the olivary bodies; *r*, the large nucleus of the pyramid; *s*, *s*, *s*, the small nuclei of the pyramid; *u*, a mass of grey substance near the nucleus of the olives (*Oliven-Nebenkern*); *u*, *q*, *r*, are traversed by numerous fibres passing in a transverse semicircular direction; *v*, *w*, arciform fibres; *x*, grey matter near the root of the vagus.

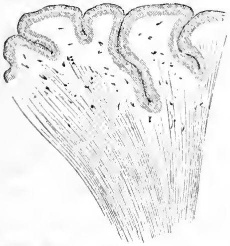
structure, as viewed by a magnifying power of ten diameters. Nothing can be more true to nature, so far as it goes, but its correct explanation must be sought for by diligent investigation with high powers. Numerous bloodvessels penetrate the central matter of the medulla, and no doubt many of the lines, which Stilling supposes to represent fibres, are in reality vessels passing to the grey matter.

The mesocephale has very much the same kind of structure as the medulla oblongata; transverse fibres (those of the pons) at its anterior part, longitudinal ones just behind these (pyramids), with vesicular matter freely intermixed. Its posterior part is the same in structure as the optic thalamus, and consists of numerous fibres with an abundant quantity of grey matter. The inferior layer of the crus cerebri is purely fibrous; its superior portion is identical in structure with the optic thalamus, and the locus niger contains large caudate nerve-vesicles, with a considerable quantity of pigment contained in them.

Microscopic investigation has as yet thrown no light on the *direction* and *connections* of the fibres of the cerebrum or cerebellum. What is known upon these points is derived from coarse dissection. The tubular fibres of which the white matter is composed, appear to be disposed on different planes, and perhaps interlace with each other, so as to render it difficult to isolate any plane to any great extent. This arrangement is more obvious in the cerebellum than in the cerebrum. The grey matter of both these segments contains the ordinary elements, caudate and spherical vesicles; but in the cerebellum those of the latter variety are much larger and more distinct than those which are met with in the brain. The peculiar structure of particular parts, as the optic thalami, corpora striata, tuber cinereum, &c. has been already described.

The grey matter of the convolutions of the brain presents the same characters throughout, excepting in certain convolutions of the posterior lobe near the posterior and inferior horns of the lateral ventricles. Here, we may observe, in a horizontal section, the grey matter of the convolutions separated into two portions by a delicate white line, well represented in *fig.* 398. This layer of light matter was first

Fig. 398.



a White line in the grey matter of convolutions of the posterior lobe.

described by Vicq d'Azyr, but has attracted very little attention from subsequent anatomists. I have never looked for it without finding it. It consists of nucleated particles, similar to those in the grey matter of the cerebellum. The layer of grey matter external to it contains few nerve-fibres; that internal to it contains them in great numbers, passing into it at right angles.

It is not intended in this part of the article to discuss the physiology of the brain. But in order to develope more clearly than can be done in a mere description the connection of its several parts and the views of its structure which I believe to have the best foundation, I shall state briefly what appears to be the probable *modus operandi* of the organ, whether as the source of voluntary action or as the recipient of sensitive impressions.

It will be necessary first to state the following propositions as *postulates*.

1. The vesicular matter is the source of nervous power. In mental actions it is the part immediately associated with changes of the mind: whether in the working of the intellect, or in the exercise of the will, or in the perception of sensitive impressions.

2. The convolutions are the parts immediately concerned in the intellectual operation.

3. The simple exercise of the will, for a voluntary movement, is probably connected with the corpora striata.

4. The mere reception of sensitive impressions is connected with the optic thalami and the superior layer of the crus cerebri.

5. Mental emotions affect the posterior and superior part of the mesocephale.

6. The cerebellum is the regulator of the locomotive actions.

These propositions, which, it is admitted, although not improbable, are far from being proved, will serve as the basis of an hypothesis of the action of the brain.

In simple operations of thought, as in the exercise of the reasoning powers, or of those of the imagination, the convolutions of the brain are immediately engaged. We do not say that material changes give rise to the mental actions, but rather that the changes of the immaterial mind and those of the vesicular matter of the convolutions are simultaneous.

If an intellectual act gives rise to the exercise of the will, the change in the superficial vesicular matter is propagated by the fibres of the hemisphere to the corpus striatum, whereby the will is excited, and the change in the vesicular matter of that body is propagated along the inferior layer of the crus cerebri, and, after passing through the mesocephale, along the anterior pyramids to the spinal cord, each anterior pyramid acting upon that antero-lateral column of the cord which is on the opposite side of the body to itself.

The pyramids connect the vesicular matter of the corpora striata with that of the spinal cord; from their small size it is highly improbable that they can be viewed as continuations of spinal nerves up into the brain.

Simple solution of continuity of the fibres of the hemispheres, which does not cause pressure, nor affect in any way the corpora striata, would therefore merely cut off the communication between the seat of intellectual action and the centre of voluntary action. The will, although unaffected, is unable to keep up with the train of thought, and mental confusion is the result. The loss of speech, which sometimes precedes a paralytic attack, and which may remain even after the paralysis has been removed, may be accounted for in this way. The intellect is competent to shape the thought, but unable to excite the will, upon which the exercise of the organs of speech is so obviously dependent.

Changes, originating or excited in either hemisphere, may be propagated to the corresponding parts of the other hemisphere by the transverse commissures, the corpus callosum, anterior commissure, &c. How far both hemispheres are in simultaneous action, during the rapid changes of the mind in thought, can scarcely be determined; it seems probable, however, that, in certain acts of volition, one only is the seat of the change which prompts to the movement. If I will to move my right arm, the change by which that movement is prompted belongs to the left hemisphere and corpus striatum.

Certain cases of disease confined to one hemisphere, in which a considerable degree, at least, of intellectual power persists, denote that the sound one may suffice for the manifestation of the changes connected with thought, and it may be reasonably supposed that the sound hemisphere may excite to action the centre of volition (corpus striatum) on the diseased side.

The existence of hemiplegic paralysis, then, implies an affection, *direct* or *indirect*, of the centre of volition (corpus striatum) on the opposite side. Pressure, or a morbid change in the physical state of its tissue originating in it or propagated to it, is all that is necessary for this purpose; and this change, like the change in the normal actions, may be of such a kind as to elude our means of observation.

When a sensation is excited, the stimulus acts from periphery to centre. The change is propagated by the sentient nerve to the optic thalamus, which, by its numberless radiations and its many commissures, is well calculated to excite all parts of either hemisphere, and even of both hemispheres. When the nerve excited is one of pure sense, the change is wrought more directly in the brain; if the fifth, or any of the nerves of the medulla oblongata, the stimulus acts directly on the part; but if a nerve of either limb be stimulated, the change must be propagated through the spinal cord.

It will be asked, if this be the *modus operandi* in sensations, how does it happen that disease of one optic thalamus does not impair sensation in one-half of the body? And how is it that such disease is much more frequently associated with hemiplegic paralysis, of a kind not to be distinguished from that which depends on diseased corpus striatum. The answer to the first question is as follows. The optic thalamus, or, more properly, the centre of sensations, is never wholly diseased, for this centre is not confined to the optic thalamus of descriptive anatomists, but extends to the mesocephale and olivary columns. Extensive disease of this centre would probably be fatal to sensation. But the most ample provision exists for opening up new channels of sensation if those on one side or a part of them be impeded. The centres of opposite sides are intimately connected, especially in the medulla oblongata and mesocephale, by commissural or by decussating fibres; the optic thalami of opposite sides are connected to each other by the posterior commissure and the soft commissure, and the immense multitude of fibres which radiate from each thalamus insure its connection with a considerable extent of the brain, so that a change in any part of it cannot fail to be communicated to some portion of the hemisphere. It is sufficient for mere sensation that the centre of sensibility should be affected. Intellectual change resulting from that affection depends upon fibres which radiate between it and the optic thalami.

It often happens that at the onset of a cerebral lesion *sensation* as well as motion is paralysed in the opposite side of the body. In a few days, however, the sensibility returns whilst the paralysis of motion remains,—a fact which is sufficient to show that the motor and sensitive power must have different channels in the centres as well as in the nerves. The primary paralysis of sensation may be due to a lesion on one side affecting the centre of sensibility, or to the shock which that centre may have received from the sudden occurrence of lesion in some other neighbouring part. In the latter instance the recovery of sensibility takes place evidently on the subsidence of the effects of shock: in the former it may depend on the existence of other channels of sensitive impressions, independently of those involved in the lesion. Hence there may be lesion of one optic thalamus without loss of sensibility.

The answer to the second question is obtained from considering the intimate connection of the corpus striatum and optic thalamus. No two parts of the brain are so closely united by fibres in vast numbers passing from one to the other. Disease of the thalamus therefore may excite a morbid state of the corpus striatum, without producing any change in its structure, which may be recognised by the ordinary means of observation. And thus hemiplegia will take place, and remain as long as the morbid state of the corpus striatum remains. A lesion of the corpus striatum may in a similar manner affect the optic thalamus of the same side; but as that is not the only channel of sensitive impressions, a loss of sensibility does not necessarily occur.

Emotions are for the most part excited through the senses. A tale of woe, a disgusting or painful spectacle, a feat of wonderful power or skill, the sudden appearance of a person not expected, are calculated to produce corresponding emotions of pity, disgust or pain, wonder or surprise. But emotions may likewise be produced by intellectual change. The workings of the conscience may remind one of some duty neglected or some fault committed, and the emotion of pain, or pity, or remorse may ensue. Now emotion may give rise to movements independently of the will. The extraordinary influence of emotion on the countenance is well known, and this may affect one side of the face, which is paralysed to the influence of the will, or it may excite movements of the limbs, even when the will can exert no controul over them. From these facts it is plain that that part of the brain which is influenced by emotion must be so connected that the convolutions may affect it or be affected by it; that it may be readily acted on by the nerves of pure sense; that it may influence the spinal cord and the motor nerves of the face when the ordinary channels of voluntary action have been stopped. No part possesses these conditions so completely as the superior and posterior part of the mesocephale, which we have already noticed as concerned in acts of sensation. Is an emotion excited by an impression made upon one of the senses? this part becomes directly affected, and through the optic thalamus the emotional feeling causes intellectual change. The working of the intellect on the other hand may act on the seat of emotion through the same channel. And an excitement of this part may produce movement of a limb, or of all the limbs, through its influence on the spinal cord through the olivary columns.

The cerebellum influences the antero-lateral columns of the cord, partly through the deep fibres of its great commissure, the pons Varolii, which interlace freely with the fibres of the anterior pyramids, vesicular matter being interposed, and partly through those portions of the restiform bodies which penetrate the antero-lateral columns of the spinal cord. It associates and harmonizes the movements of the trunk, and especially those of the lower extremities, for locomotion, through those portions of the restiform bodies which are continued with the posterior columns of the cord.

The crossed influence of deep lesion of either hemisphere of the cerebellum is difficult to explain in the absence of any proved decussation of the restiform bodies. The connection of the deep fibres of the pons, however, with the anterior pyramids in the mesocephale does afford some explanation. If, for instance, the left cerebellar hemisphere be the seat of lesion, these fibres will be affected, and they may influence the fibres of the left pyramid, which again will affect the right half of the cord and the right side of the body. Those fibres of the restiform bodies which incorporate themselves with the antero-lateral columns, are doubtless too few to produce much influence.

Abnormal anatomy of nerves and nervous centres.—The great space already occupied by this article obliges me to compress into as small a compass as possible the observations which I propose to make under this head.

An interesting preliminary question is to determine to what extent nervous matter is capable of being regenerated, when any solution of its continuity may have occurred. In nerve it has long been proved that such regeneration is capable of taking place. If the nerve be simply divided, without loss of substance, union may take place immediately; but if a piece of it have been cut away, a considerable period must elapse before its complete restoration. This was satisfactorily proved by Dr. Haighton's* experiments, in which he found that the function of the inferior laryngeal nerve in dogs was restored six months after division of the vagus, but with altered tones. Tiedemann divided in a dog the nerves of the forefoot and leg, and at the expiration of eight months observed that sensation and motion returned; after twenty-one months the sensitive power had increased considerably, and at length the dog regained the complete use of his foot. Schwann divided both sciatic nerves of a frog, in the middle of both thighs: immediately after the operation the frog's movements were very imperfect; after a month it had gained some power; but in three months it leaped as well as if no division had taken place. The sensibility of the foot, which was destroyed by the section, became nearly entirely restored; and irritation of the nerve with a needle above the cicatrix produced strong contractions in the muscles supplied from the nerve below the wound. On examination with the microscope, Schwann found that the cicatrix consisted of true nerve fibres disposed in their usual way.†

* Phil. Trans. 1795.

† Quoted in Müller's Physiology.

Müller mentions the interesting fact of the return of some degree of sensation in the flaps of skin used for the Taliacotian operation for a new nose, as an argument in favour of the reproduction of nerves. Dieffenbach, however, who has had so much experience in these operations, states that the return of sensibility is only very imperfect, which is to be expected, since the divided extremities of the same fibres cannot re-join, except in very small number.

The evidence of restoration of function in divided nerves in the human subject is imperfect, although not opposed to what has been above stated. Gruithuisen's observations on the consequences of an accidental division of the dorsal nerve of the thumb in his own person are sufficiently conclusive. Eight months after the division, although the sensation had returned, it was so imperfect that the mind could form no conception of the precise point stimulated, as if the isolation of the fibres so necessary to exact sensation had been destroyed in the cicatrix, or as if the fibres of the peripheral portion of the nerve had not united with the corresponding ones in its central portion. Mr. Earle relates a case in which a part of the ulnar nerve was cut out; at the end of four years the little finger was useless, and the sensations very imperfect.

Indeed there is much difficulty in drawing conclusions from the restoration or non-restoration of function after division of nerves, for no artificial disposition of the cut extremities will insure the corresponding fibres meeting. A sensitive fibre may be joined to a motor, and thus the office of both would be neutralised; or different sensitive fibres might unite, from which doubtless some confusion as to the nature and position of the impression would ensue.

The microscopic examinations of Seinruch, Hermann, Nasse, and Klencke have rendered it certain that true nerve-fibres are reproduced in the cicatrix of a divided nerve. Nasse states that they are smaller than the natural size; and he has likewise pointed out an interesting fact, in the decrease of size of the fibres of the peripheral segment of the nerve as compared with those of the central segment, showing that a certain degree of atrophy takes place in that portion of the nerve, even after it has been separated for a short period from its connection with the nervous centre. This author never saw sensation and motion return, although he kept the animals for three quarters of a year. Perhaps this was owing to his having removed large portions of the nerves he operated upon.

With respect to the reproduction of solutions of continuity in the nervous centres, what little is known must be viewed as unfavourable to the supposition that perfect restoration of the lost parts takes place. If the brain or spinal cord be wounded, union will take place; but it does not appear from Arnemann's observations nor from Flourens's that the uniting substance is true nervous matter. Further researches are much needed upon this interesting subject.

Abnormal anatomy of the spinal cord and its membranes.—The membranes of the spinal cord are liable to those morbid changes which commonly affect the tissues of the same kind occurring in other parts of the body.

Inflammatory affections of the dura mater are exceedingly rare, and occur chiefly in connexion with wounds or injuries of the spine, or in extension of disease from the bones. Occasionally but very rarely we find osseous or cartilaginous deposits upon it, which are most obvious on its arachnoid surface. Blood is sometimes, but not frequently, effused externally to it, and effusions of serous fluid are still more rare. Such effusions, from the usually dependent position of the spinal canal, and from the large venous plexus which exists around the dura mater, are very likely to be pseudo-morbid, resulting from the gravitation of the fluids after death. Cancerous or fungoid tumours may originate from the dura mater, or may arise externally and grow to it afterwards. Tubercles may form between the dura mater and its arachnoid lining.

When a deficiency of more or less of the posterior osseous wall of the spinal canal occurs, we find a corresponding dilatation of the dura mater and arachnoid sac, which, being filled with water, causes an external tumour, constituting what has been called *Hydrorachis*, the consequence of *spina bifida*. These tumours are altogether dependent on the congenital imperfection of the bones of the spine, and whatever peculiar disposition of the spinal cord or its nerves may be found within them is due to an arrest of or a disturbance in the process of developement of those parts. The details of the anatomy of these tumours will be found in the article SPINE.

The arachnoid.—The spinal arachnoid exhibits marks of the inflammatory process more frequently than the dura mater. But in neither membrane does this state of disease occur often, except as a complication of injury or of a morbid state of other parts, either of the vertebral column or of the spinal cord itself. The signs of an inflamed state of this membrane are lymph effused on its free surface, recent, or indurated causing more or less thickening. Adhesions between corresponding parts of the two arachnoid layers are also a good indication of a previously existing inflammation. But care must be taken not to mistake the adhesion, which is often found between points of these membranes, for inflammatory adhesion. The former occurs in minute points, and is probably a result of drying of the membranes at the points of contact; the latter is always accompanied by the formation of new matter which forms the medium of union between the layers.

Cartilaginous spots are by no means unfrequently found on the arachnoid membrane, chiefly in connection with its visceral layer. They are generally small detached laminæ thoroughly incorporated with the membrane, rarely exceeding in size the flat surface of a split pea, more frequently much smaller. They generally occur on the posterior surface of the arachnoid. I have seen such deposits in cases where there were no previous symptoms to denote any affection of the central nervous system, and I am disposed to believe that such deposits, separated as they must be from the surface of the cord, are not likely to occasion much if any irritation to that organ. They are found mostly in the dorsal and lumbar regions. Sometimes spots of bone, of similar size and shape, are found scattered over the membrane.

The pia mater.—The spinal pia mater being the seat of the vascular ramifications which contribute to the nutrition of the cord, is also subject to congestions often depending on causes quite extraneous to the spinal canal or cord. Thus the congestions which are produced in animals drowned, or asphyxiated in any other way, exist in the vessels of this membrane. The most frequent cause of congestion in these vessels, however, is the position of the corpse after death. After deaths, preceded by violent convulsions, there is always congestion of the vessels of the pia mater. But this congestion must be regarded as a consequence, not as a cause of the convulsions. The holding of the breath, which accompanies continued convulsions, gives rise to a very general congestion of the venous system.

When the congestion is very considerable, it may occasion rupture of bloodvessels and effusion of blood into the sub-arachnoid cavity. This constitutes a form of *spinal apoplexy*, which is apt to follow concussion of the cord, caused by a fall or by a blow inflicted upon the back. It may follow any of those diseases which are accompanied by convulsions—tetanus, hydrophobia, epilepsy, cerebral apoplexy.

Inflammatory affections of the membranes, deposits of tubercle or other foreign matter which may cause induration of the cord, have their primary seat among the vessels of the pia mater. Inflammation of the membranes is more apt to occur among children than in adults.

Abnormal anatomy of the spinal cord.—The *absence* of this organ *(amyelia)* occurs chiefly in anencephalous fœtuses. In such cases the posterior wall of the spinal canal is often deficient, and the canal is occupied by a reddish, vascular pulpy substance. It is a question whether the absence of the cord, in such cases, is to be attributed to a real defect of its developement or to its destruction while yet in a very delicate semi-fluid state, by the formation of a dropsical effusion, either around it or in the canal or ventricle which exists in it at an early period of its developement. This latter explanation is rendered probable by the fact that all the recorded cases are of fœtuses which had reached an advanced period of intra-uterine developement; and in some of them movements had been distinctly felt by the mothers, which could not have taken place with a combined or definite character without the existence of the cord. And in some of the records it is affirmed that the children lived some hours and exhibited movements and even signs of sensation, or at least of excitability to stimuli. Such phenomena, if true, leave us no alternative but to suppose that the whole cord could not have been absent—some portion must have existed as the centre of these movements, but, being of small size, it escaped the notice of the observer.

This explanation is likewise confirmed by the occurrence of cases (rare, it is true) in which the brain existed, but the spinal cord was wanting. A very able narrative of a case of this kind has lately been published by Dr. Lonsdale of Edinburgh. "The anterior and middle lobes of the brain appeared to be properly developed, and occupied their usual positions in the cranial cavity; whilst the posterior lobes were much smaller, and were partially squeezed through a large abnormal opening or deficiency in the occipital bone. The cerebellum and that part of the occipital bone in which it is normally lodged, were wanting. There was not the slightest vestige of medulla oblongata or spinal cord, and the posterior arches of the vertebræ did not exist."* The fœtus had reached its full term, and its body and limbs were well formed.

An interesting feature which had been well observed in this case, although probably not peculiar to it, but hitherto overlooked, was the relation of the nerves in the cranial and spinal cavities. All the nerves of the medulla oblongata, and the first, second, and third cervical nerves, hung as loose threads in the cranial cavity or in the upper part of the spinal canal, and presented a looped arrangement, seeming to denote that such is their normal disposition in the nervous centre.

Partial deficiencies of the spinal cord, although also rare, are more frequent than the total absence of the organ. These occur in connection with other defects of developement. Thus, in spina bifida much of the cord is deficient, either throughout its entire extent or in those parts where the vertebral wall is defective. In such cases it is probable that the deficiency is attributable to the destructive influence of the dropsical effusion rather than to an original defect of the organ. In cases in which the upper or the lower extremities have not been developed, the usual cervical or lumbar swelling is imperfectly developed, owing to the absence or atrophy of the fibres which would have formed the nerves to those limbs.

Excessive congenital developement of the spinal cord occurs only in those monstrosities which arise from the junction or fusion of the spinal columns of two embryos.

The diseased states of the spinal cord may be enumerated as follows:—hypertrophy, atrophy, induration, softening, suppuration, deposits of tubercle or of other morbid products.

In hypertrophy, the cord is enlarged and looks full and plump, without any alteration of its consistence or of its intimate structure. It is not improbable that the elementary fibres as well as the vesicles of grey matter may be enlarged in such cases, and that the increased dimensions of the whole organ must be attributed to this cause, and not to the deposition of any new material in it. I have not, however, had any opportunity of ascertaining this point by microscopic examination.

* Edin. Med. and Surg. Journal.

Atrophy occurs in the cord generally as the result of some local pressure from a tumour developed in connection with some one of the membranes or external to them. In a case of this kind which I lately examined, the tumour consisted of a mass of scrofulous matter situate between the vertebræ and the dura mater in the upper part of the dorsal region. That part of the cord which was pressed upon by the tumour was wasted to one-half its natural size, whilst below it the cord exhibited its natural size.

Atrophy of the cord occurs as part of that general wasting of the nervous centres which accompanies advanced life, or a state of general cachexy. In persons long bedridden the cord is found in a wasted state; and in cases of extensive hysterical paralysis, in which exercise of the enfeebled limbs has been neglected, the cord will participate in the wasting of the nerves which supply the affected parts.

Induration of the cord is not of unfrequent occurrence, and appears to be the result of some abnormal nutrition analogous to if not identical with chronic inflammation—inflammation modified, perhaps, in the nature of its event by some peculiar state of the blood. The hardness occurs generally in patches, involving more or less of the thickness of the cord, and affecting the peripheral parts of the body, in proportion as it involves the immediate points of implantation of the roots of the nerves, or those roots themselves. It is generally accompanied by some discolouration of a light brownish hue, as if the first changes which gave rise to it were attended with extravasation of the colouring matter of the blood.

Sometimes, however, induration seems to result from the changes which accompany atrophy of the cord, as if from an imperfect supply of the fluids necessary for perfect nutrition.

Softening of the cord is found in two states, which are probably essentially different in their intrinsic nature and origin. One is that of red softening; the other is that of white or colourless softening. In the former the tissue of the spinal cord is much softer than it ought to be, and is readily disintegrated by a stream of water directed upon it; its colour is due to the full injection of the bloodvessels which traverse it, or to some extravasated blood. In the latter the nervous matter is reduced to a soft semifluid mass, like thick cream, without the least appearance of injected vessels. In the former the nerve fibres are more or less broken down and softened; in the latter there is little or no breaking down of the fibres, but they are attenuated and have lost the distinctive characters of the white substance and central axis to a greater or less degree. Red softening appears to be inflammatory in its origin, but white softening indicates a deficient supply of blood, and so far resembles the gangrene which occurs in external soft parts.

The anatomist should be prepared to distinguish the white softening, which is the product of a morbid process during life, from that which occurs after death as the result of decomposition, or which may be produced by violent compression of a part of the cord in opening the spinal canal. The softening which results from decomposition, in general, occupies the greatest part of the cord or the whole of it, and does not exhibit so pure a white colour as the morbid softening. It sometimes has a greenish or a dusky hue, and is more or less fœtid. The softening from injury is very circumscribed, and is surrounded by nervous matter perfectly healthy in colour and consistence. There is, moreover, generally evidence of injury to and rupture of the pia mater, the softened matter of the cord protruding through the rent in this membrane. Where the softening is morbid, it wants the abruptness which occurs in the latter case, and the diseased part gradually passes into healthy structure.

The inflammatory softening is sometimes infiltrated with purulent matter, which, if not recognizable by the naked eye, may be easily detected by the microscope and by reagents. In rare cases the pus is collected into a circumscribed abscess, occupying more or less of the thickness of the cord.

The cord may be the seat of an effusion of blood, and may thus present the condition of apoplexy, like that which is of so frequent occurrence in the brain. In such cases there may be more than one small clot occupying the central part of the cord. They are of rare occurrence, and are generally found in the upper part of the cord.

Tubercle may occur in the cord, and, as in the brain, connected with the pia mater, either deposited in a group or forming a mass which gradually encroaches upon the substance. The cervical region is that in which it most frequently is found, and it forms tumours of various sizes, each of which is generally enclosed in membranous cyst.

Cancer of the cord is a lesion of extremely rare occurrence. Ollivier relates several cases of it, but Rokitansky remarks that he has seen but one example of a cancerous tumour in the spinal cord. It is in cases where the cancerous diathesis prevails, and where cancerous matter is deposited throughout various parts of the body, that we may look for it in the cord.

Abnormal anatomy of the brain and its membranes.—The remarks already made with reference to the membranes of the cord apply equally to those of the brain. The latter membranes, however, are more frequently found in an abnormal state than the former.

The dura mater.—There may be a general or partial deficiency of the dura mater and of the other membranes according as there is a general or partial defect in the brain itself.

The partial defect is mostly observed in the falx cerebri or in the tentorium cerebelli. The cribriform appearance of the former process is of frequent occurrence and is unaccompanied by any obvious defect in the brain, and sometimes even a considerable portion of it is wanting, while the brain is quite normal.

Acute disease of the dura mater is rare, and only occurs as an effect of wounds or injuries of the cranium, or in connection with syphilitic or strumous disease of the bones; or, independently of diseased bone, as an effect of the syphilitic poison, like that which occurs on external fibrous membranes. A syphilitic inflammatory state of the dura mater is frequently the cause of serious affection of the brain. A condition analogous to that of *node* will cause pressure on the brain and paralysis; and, whilst it resists the ordinary antiphlogistic treatment, will speedily yield to antisyphilitic remedies, such as mercury and iodide of potassium.

We meet with great variety as regards the firmness of adhesion of the dura mater with the cranium. There is a tendency in some perverted states of nutrition for this membrane to become incorporated with the inner table of the skull. This seldom takes place continuously, but in patches, so that in removing the calvaria a portion of the inner table of the skull remains in connection with the fibrous membrane, or a hole is left in the latter when the conversion of the fibrous membrane into bone may be complete. It is in the more advanced periods of life that this morbid condition is chiefly found; indeed we seldom open the skull of a person who has passed the age of threescore without finding more or less of it. At that period of life it may be regarded rather as one of the series of changes which accompany advancing years than as a diseased state. When, however, it occurs at the earlier ages, it must be viewed as resulting from a morbid process.

Patches of bone are frequently found in the processes of the cranial dura mater, as in the falx, tentorium. They occur more frequently in the former than in the latter. In size they vary much: they are placed between the layers of the dura mater, and are completely enclosed by them; sometimes, however, they encroach upon these layers, which then seem as if they had been completely converted into bone.

Fibrous tumours are sometimes formed at various parts of the dura mater. These vary considerably in size and number. They project inwards upon the brain, and indent that organ more or less according to their size, and sometimes they project outwards, and by causing absorption of the bone by pressure form depressions for themselves, and even wear holes in the bone by their outward growth.

Tubercles of a strumous character are sometimes deposited in connection with the dura mater. The most remarkable example I have seen of these morbid tumours is a preparation in the museum of King's College, London, taken from a patient who suffered severely from epilepsy. The internal surface of the dura mater and of the falx is covered with numerous tumours of this kind, some of which are nearly as large as a walnut, others not larger than a small filbert. This specimen belonged to the collection of the late Dr. Hooper, who has given an excellent delineation of it in his plates of the morbid anatomy of the brain.

The dura mater participates in the diseased states of the cranial bones. Cancer or fungoid disease affecting the calvaria or any part of the cranial wall which is covered by dura mater, will extend to the dura mater and subjacent parts.

When there has been a solution of continuity and a loss or removal of any portion of the cranium, the exposed surface of the dura mater is apt to throw out a growth of granulations which constitute *the fungus of the dura mater*, analogous to that which sprouts from the surface of a similar fibrous membrane—the tunica albuginea of the testicle. In point of structure this fungoid growth is the same as the granulations on the surface of external ulcers.

Effusion of blood, constituting a form of meningeal apoplexy, may occur on the external surface of the dura mater separating it from the bone; or on its internal surface, dissecting away the arachnoid membrane from its adhesion to the dura mater. The former kind is mostly if not always traumatic, that is, resulting from the application of violence to the exterior of the cranium The latter kind is of extremely rare occurrence, and must be carefully distinguished from that variety of effusion into the arachnoid sac in which the effused blood appears to be covered by a serous membrane. This membrane, however, results from the condensation of the superficies of the clot by its friction against the parietal arachnoid, and it may be distinguished from a true serous membrane by the absence of epithelium from its free surface. Effusions of either kind generally occur on some part of the surface of the cerebral hemispheres above the level of the petrous bone.

The arachnoid membrane. — The arachnoid membrane is sometimes the seat of acute inflammation, and presents the same signs of that process as are met with in other serous membranes. The chief and, indeed, the only unequivocal sign of his condition as of recent occurrence is the exudation of plastic lymph upon the free surface of either or both layers of the membrane, with or without pus. This is attended with a highly injected state of the subjacent tissue (pia mater or dura mater, generally the former). The arachnoid itself, it will be remembered, contains no bloodvessels, but derives its nourishment from the vessels of the subserous tissue. Its apparent vascularity is due to its great tenuity and transparency, which allow the bloodvessels lying underneath to be seen through it as if they belonged to the membrane itself.

An opaque condition of the arachnoid, varying both in degree and extent, is a very common appearance of this membrane, especially at the middle and advanced periods of life. This occurs sometimes in patches; at other times it is generally diffused over the whole membrane. It is most conspicuous on the convex surface of the brain, especially towards the great longitudinal fissure, and it is frequently associated with large and numerous Pacchionian bodies. It occurs, however, very commonly at the base, and frequently opposite the confluxes of the subarachnoid fluid.

The opacity of the arachnoid is commonly attributed to a former acute inflammation of the membrane, or to a chronic inflammation going on up to the time of death. But this state of the membrane is of such frequent occurrence, and is so often found in persons who evinced no sign of important organic change during life, that it seems scarcely correct to attribute it to such a cause. It is not meant to deny that previous inflammation or chronic inflammation is capable of causing these opaque spots, but undoubtedly other causes may produce them as well. The friction of two opposed surfaces may do it, and deposits upon the free surface of the membrane, an altered condition of the epithelium, may have the same effect. Some recent microscopical examinations convince me that morbid deposits similar to those which are formed on the coats of arteries, may be found here, and occur in those morbid states of the blood, and consequently of the whole system, which are favourable to the deposition of a morbid material throughout the arterial system, or in the substance of viscera.*

In confirmation of this view it may be stated that opacities of the arachnoid are most common after the middle period of life, and that they are then almost uniformly associated with a morbid state of the arteries of the brain and of other portions of the arterial system.

Adhesion between the opposed surface of the visceral and parietal layers of the arachnoid is (and the fact is curious) not of frequent occurrence, excepting at the convex border of the falx cerebri, where the Pacchionian bodies are found. And the intrusion of these bodies into the longitudinal sinus frequently increases the closeness of that adhesion. The cellular adhesion so common in other serous membranes is rarely found in the arachnoid.

Small plates of cartilage or of bone are sometimes found in connection with the arachnoid. Their formation is generally the result of a previous morbid deposit which has subsequently become converted into cartilage or bone.

Effusion.—Effusions take place either into the subarachnoid or the arachnoid cavity. The existence of serum, in undue quantity, in the former situation, must be looked on as an increase in the fluid which naturally occupies that space, and as we have already remarked in a former part of this article, it takes place in consequence of the failure of the normal pressure upon the vascular surface, and may rather be regarded as tending to preserve the functions of the brain than as producing an injurious pressure upon it. Indeed I have always found that in cases where an abnormal quantity of fluid existed in the subarachnoid cavity, the brain afforded no indication of its having experienced undue pressure previous to death. In such cases the brain seems to contain less blood than natural, and its anæmia is most obvious in the grey matter. Sometimes there is hyperæmia of the veins in the white matter of the hemispheres, as if the heart's force, more necessary to the venous circulation within the cranium than even to that of other parts of the body, had been prevented from exerting its influence through the capillaries upon the blood in the veins.

* It is probably to deposits of this kind that Rokitansky refers under the title of "Gallenfettige Concretionen."

The existence of serous fluid in the arachnoid cavity is of very rare occurrence. In some instances old adhesions of the two layers of arachnoid to each other circumscribe a space in which fluid accumulates.

Blood is sometimes effused into the subarachnoid cavity. This is frequently the case in injuries of the head, the blood escaping from broken vessels of the pia mater. Sometimes the blood effused into either lateral ventricle will escape into the subarachnoid cavity, breaking down the membrane of the ventricle. If an apoplexy occur near the surface of the brain, the laceration of the cerebral substance may extend quite to the surface, and the blood may pass through the pia mater into the subarachnoid space.

In some instances we find blood in the cavity of the arachnoid (the arachnoid sac). The blood is either loose in the sac, or it is more or less closely connected with the inner surface of the membrane lining the dura mater.

In a recent communication from Mr. Prescott Hewitt, published in the last volume of the Medico-Chirurgical Transactions, the principal facts relating to this subject have been collected and arranged in an interesting form. Mr. Hewitt describes these effusions of blood as existing in four forms:—

"1. The extravasated blood may be either liquid or coagulated; if in the latter state, it may be in clots, or spread out in the shape of a thin membranous layer, covering a greater or less extent of the surface of the brain.

"2. Sometimes the extravasation presents itself under the shape of a false membrane, possessing more or less of the original colour of the blood.

"3. The blood may be fixed to the free surface of the arachnoid and there maintained by a membrane, which to the naked eye presents all the characters of the serous membrane itself.

"4. The blood is frequently found enclosed in a complete cyst of various degrees of thickness, which may be removed unbroken from the cavity of the serous membrane.

"The four divisions above referred to," adds Mr. Hewitt, "may be and often are combined with each other, but in whatever state the extravasated blood has been found, it has, in the majority of cases, corresponded to the upper surface of the brain, and has been rarely met with in the cerebellar fossæ."

It is impossible that these effusions of blood can have any other source but the minute bloodvessels of the pia mater or the dura mater, which becoming ruptured allow the blood to burst through the serous membrane by which they are covered. They occur mostly in persons of a scorbutic or hemorrhagic habit, or in whom the arteries have become brittle from abnormal deposits in them; and it is not improbable that whilst the imperfect nutrition of the arteries is going on, the serous membrane itself suffers, becomes wasted, and therefore easily yields to the force of the blood as it escapes from the bloodvessels.

Pus is found in the subarachnoid cavity where there has been inflammation of the pia mater and arachnoid, and more rarely in the arachnoid sac.

Of the pia mater.—This membrane being the vascular membrane of the brain, and containing the nutrient vessels as well of the surface of the brain as of the visceral layer of the arachnoid, is the seat of all those changes in the condition of the bloodvessels or of their contents, which give rise to, or are caused by, morbid states either of the nervous matter or of the serous membrane.

All those changes which indicate hyperæmia or anæmia of the convolutions of the brain occur in the pia mater; and the colour of this membrane will vary according to the quantity of blood contained in its bloodvessels.

There are no definite signs which enable the anatomist to pronounce whether an hyperæmia be of the active and inflammatory kind, or passive, and dependent on some cause remote from the brain itself, or even upon a post-mortem cause, unless it be accompanied with those undoubted products of the inflammatory process, pus or lymph.

A highly injected state of the vessels of the pia mater will frequently be caused by the manner of the patient's death. Where the respiratory actions have been laboured and difficult prior to death, this is sure to occur: we find it also when death has been caused by asphyxia, however produced.
